child's mental status, including the GCS score. For children with moderate to severe head trauma (defined as GCS scores 3–13) emergent neuroimaging should be obtained, as the risk of intracranial injury is substantial (please refer to Chapter 246, Severe Head Trauma) (4,12). A detailed physical examination of the head should be conducted to explore for any scalp hematoma, ecchymosis, lacerations, evidence of skull fracture, hemotympanum, and other signs of basilar skull fractures. A complete neurologic examination including level of consciousness, as well as motor and sensory deficits, should be documented.

There have been several large, prospective observational studies in the past decade that have greatly helped clinicians evaluate children with blunt head trauma for the risk of TBI. One study developed two age-based rules, with a goal of identifying children at very low risk for clinically important TBIs who do not require emergent neuroimaging (3). These prediction rules were derived and validated in a prospective multicenter study of more than 42,000 US children with head trauma and GCS scores of 14 to 15, seen in the EDs in the Pediatric Emergency Care Applied Research Network (PECARN). The factors for these two age-based prediction rules are presented below under "Key Testing." The sensitivities of the age-based rules, one for children 2 through 17 years, and the other for children younger than 2 years, were between 97% and 99%, and the negative predictive values (NPV) were nearly 100%, with narrow confidence intervals (CI). Most importantly, in both age groups, in the absence of any of the PECARN prediction rule factors, the risk of clinically important TBI was on the order of 1:2,000 to 1:5,000; therefore, cranial CT imaging is not routinely recommended for children with no PECARN risk factors (Fig. 247.1) (3).

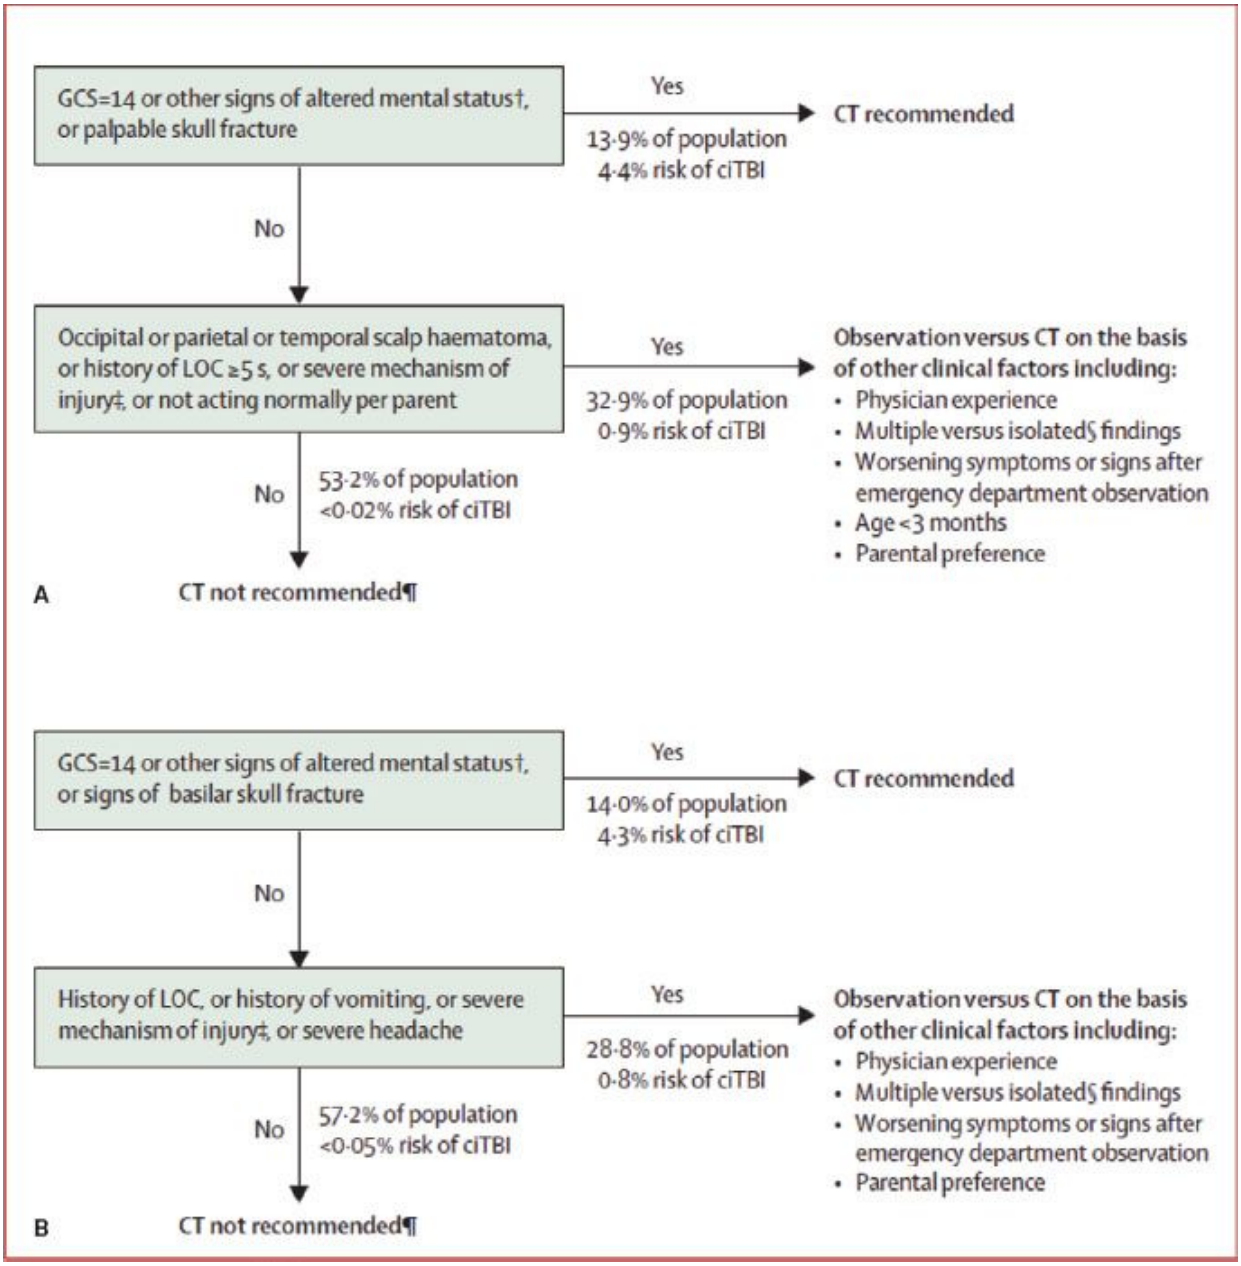

FIGURE 247.1 Suggested CT Algorithm for Children Younger than 2 Years **(A)** and for Those Aged 2 Years and Older **(B)** With GCS Scores of 14–15 After Blunt Head Trauma[3] Reprinted from The Lancet, Vol. number 374, Kuppermann N., Holmes JF, Dayan PS, et al., Identification of children at very low risk of clinically-important brain injuries after head trauma: a prospective cohort study, Pages 1160–1170, Copyright 2009, with permission from Elsevier.

In contrast to the PECARN prediction rules, which focus on identifying children at very low risk of clinically important TBI not requiring CT, two other rules focus on identifying children with significant intracranial pathology. The Children's Head Injury Algorithm for the Prediction of Important Clinical Events (CHALICE) was derived from a multicenter cohort of English children <16 years with a history or signs of head trauma (13); however, the complexity of the rule makes clinical implementation challenging. Another rule, the Canadian Assessment of Tomography for Childhood Head injury (CATCH) rule, was derived from a prospective multicenter cohort of Canadian children with blunt head trauma presenting with GCS scores of 13 to 15 and a history of LOC, amnesia, disorientation, persistent vomiting, or irritability (4). In this rule, the main outcome was need for neurosurgical intervention, and the variables associated with this outcome and for which a cranial CT is recommended include: a GCS score <15 2 hours after injury; suspected open/depressed skull fracture; history of worsening headache; or irritability on examination. This rule had a sensitivity of 100% (95% CI 86.2 to 100) (4). Although these last two rules have a high sensitivity for identifying children with significant TBI, only the PECARN prediction rules focus on children with minor head trauma, defined by GCS scores of 14 to 15, to identify children who *do not* require cranial CT evaluation (14,15). The American Academy of Pediatrics has identified the PECARN prediction rules in the "Choosing Wisely" campaign (16) and recommends the use of clinical observation prior to CT decision making for those children determined to be at low risk for clinically important TBI (17).

Although plain skull radiographs have limited utility in the evaluation of head trauma, for children younger than 2 years old who are asymptomatic and have only a scalp hematoma on physical examination, the use of skull x-rays (18) or point-of-care ultrasound to evaluate for a possible underlying skull fracture may be considered. Some recent studies have found point-of-care ultrasound to be an excellent test to rule out skull fractures in children (19,20). Most (>90%) linear skull fractures in children younger than 2 years of age have overlying soft tissue swelling or scalp hematomas, and

15% to 30% of skull fractures are associated with TBIs (18). Therefore, if a skull fracture is identified by either x-ray or ultrasound, a cranial CT should be obtained to assess for TBI (18). If there is no skull fracture on x-ray in an asymptomatic child with only a scalp hematoma, no further imaging is routinely required, and the patient may be discharged home, as the risk of intracranial injury is very low (21).

KEY TESTING

- Consider PECARN prediction rule factors in the decision to avoid emergent neuroimaging. Children with none of the PECARN factors are at very low risk for clinically important TBI and typically do not warrant immediate CT imaging.

PECARN Prediction Rule Factors (3)

Younger than 2 years old (pneumonic "SCALPS") (22)	Two years and older (pneumonic "BASILaR") (22)
Scalp hematoma (except frontal)	Basilar skull fracture, signs of
Caregiver concern for change in behavior	Altered mental status[a]
Altered mental status[a]	Severe headache
Loss of consciousness > 5 sec	Injury mechanism, severe[b]
Palpable skull fracture	Loss of consciousness
Severe mechanism of injury[b]	Regurgitation (vomiting)

[a]GCS <15 or other signs of altered mental status: agitation, somnolence, repetitive questioning, or slow response to verbal communication.
[b]Severe mechanism of injury: rollover/ejection/other passenger death in motor vehicle crash (MVC), fall >3 ft (for < 2 years) or fall >5 ft (for ≥2 years), nonhelmeted pedestrian/bicyclist struck by a motor vehicle, or patient struck by high impact projectile (3).

ED MANAGEMENT

In the PECARN head trauma cohort, observation of selected children was associated with decreased CT use. There was no difference in the rate of clinically important TBI between those who were observed before a decision was made on the use of CT and those who were not observed before CT decision making (17). For children who are observed and either do not improve or develop a worsening clinical picture (change in mental status, worsening headache, persistent

vomiting, or more ill appearance), cranial CT should be seriously considered.

CRITICAL INTERVENTIONS

- Cranial CT is recommended for children with persistent GCS scores <15 or altered mental status, or if there are signs of skull fracture (or if there are worsening signs or symptoms of TBI).
- Consider observation before CT decision making for children with isolated PECARN risk factors, other than those mentioned above.

Cranial CT is not recommended for children with no PECARN risk factors for clinically important TBI. These children should be discharged home, with instructions on when to return immediately (for developing signs of TBI).

DISPOSITION

Most children with minor head trauma can be discharged home (3,8). If a child with minor head trauma has a cranial CT performed with normal results, the risk of subsequent worsening is very low and the risk of requiring neurosurgical intervention is extremely low (23). Assuming a normal mental status, these children may be safely discharged home, unless they have persistent symptoms (e.g., vomiting) or develop new symptoms that require reevaluation.

Common Pitfalls

- Failure to recognize clinical deterioration, which can occur with an expanding intracranial hemorrhage, when a child presents with an initial GCS score of 15, but then deteriorates.
- Failure to recognize nonaccidental trauma, based on the history (vague or inconsistent with developmental stage or physical findings) or examination findings suggestive of inflicted trauma.

CHAPTER 248 Sports-Related Concussion

Ryan Petering and Robert Cloutier

It is estimated that 3.8 million concussion injuries occur in the United States annually, though many of these go unreported and medical care is not sought (1). Between 2001 and 2009 an average of 173,285 persons aged 19 years or younger presented to emergency departments (EDs) annually for nonfatal traumatic brain injuries (TBIs) related to sports and recreational activities (2). Annual TBI ED visit rates increased 62% during this period. American football, playground activities, basketball, and soccer have the greatest number of TBI-related ED presentations (2). The most common ages for sports-related concussion ED presentation are 14 to 18 years. Males (77%) present more frequently than females (3). However, it appears that in sports with similar rules (e.g., soccer) females have a higher number of concussions and report increased severity compared with males (4). The majority of patients with sports-related concussion (95%) are discharged home following ED evaluation (3).

This chapter discusses concussion specifically in the setting of a sports-related event. See also Chapters 246 and 247.

CLINICAL PRESENTATION

Concussion, mild TBI, and TBI refer to similar events. TBI includes all head injuries and often refers to more serious and life-threatening presentations. Mild TBI typically refers to an injury to the head, with or without loss of consciousness, and a Glasgow Coma Scale (GCS) of 13 to 15 (5). Concussion is defined as a

traumatically induced transient disturbance of brain function (4,6). It is important to note that while concussion most often occurs following a direct blow to the head, other mechanisms such as whiplash may transmit force to the head and cause concussion as well. Symptoms are typically immediate and consist largely of functional disturbances; associated structural abnormalities on imaging studies are rare (7).

Consensus concussion panels have recommended avoiding previously associated adjectives such as “mild,” “moderate,” or “severe,” as these terms have little to no prognostic value for individual patients. Unfortunately, concussions judged as “mild” may cause persistent symptoms that can last for months to years.

The symptoms of concussion are diverse and variable. It is helpful to think of symptoms in the categories of (1) physical, (2) cognitive, (3) emotional, and (4) sleep-related. Physical symptoms include headache, nausea, vomiting, balance problems, dizziness, visual problems, fatigue, sensitivity to light and/or noise, or numb or tingling sensations. Loss of consciousness can occur with concussion injuries, but is not required for the diagnosis; only about 10% of concussions are associated with a loss of consciousness (4). Cognitive symptoms include feeling mentally “foggy” or dazed, difficulty concentrating, forgetfulness, confusion about recent events, slowness in responding to questions, and repetitive questioning. Emotional symptoms include irritability, sadness, emotional lability, and nervousness. Sleep changes include drowsiness, sleeping more or less than usual, and difficulty initiating sleep.

DIFFERENTIAL DIAGNOSIS

A comprehensive primary and secondary survey should be performed to identify coexisting injuries. Among the most important to consider are fracture, intracranial hemorrhage, and structural brain damage. The past medical history should identify preexisting medical conditions that may contribute to or complicate a concussion.

ED EVALUATION

Initial ED evaluation should determine whether imaging is required. Clinical evaluation should include a thorough history to determine the specifics of the injury mechanism and the symptoms reported. Physical exam should include a comprehensive neurologic examination.

Skull radiographs are not recommended (5). A level A recommendation is given for noncontrast computed tomography (CT) for patients with loss of consciousness or posttraumatic amnesia if one or more of the following are also present: headache, vomiting, drug or alcohol intoxication, deficits in short-term memory, physical evidence of trauma above the clavicles, posttraumatic seizure, GCS score less than 15, focal neurologic deficit, or coagulopathy. The guideline gives a level B recommendation for noncontrast head CT for patients without loss of consciousness or posttraumatic amnesia if focal neurologic deficit, vomiting, severe headache, physical signs of basilar skull fracture, GCS score less than 15, coagulopathy, or a dangerous mechanism of injury (ejected from motor vehicle, a pedestrian struck, and a fall from a height of more than 3 ft or five stairs) (5).

Up to 15% of patients presenting to the ED following TBI who have a GCS score of 15 are found to have an acute intracranial lesion on head CT (8–13). However, less than 1% of these patients require neurosurgical intervention (9,10,14).

KEY TESTING

- Noncontrast head CT scan MAY BE ordered in patients WITHOUT loss of consciousness OR posttraumatic amnesia with ONE of the following: (1) focal neurologic deficit, (2) vomiting, (3) severe headache, (4) physical signs of a basilar skull fracture, (5) GCS score less than 15, (6) coagulopathy, (7) dangerous mechanism of injury.
- Noncontrast head CT scan SHOULD be ordered for patients WITH loss of consciousness OR posttraumatic amnesia and any of the above criteria or any of the following: (1) drug or alcohol

intoxication, (2) physical evidence of trauma above the clavicles, (3) short-term memory deficits, (4) posttraumatic seizure.

ED MANAGEMENT

Headache and nausea or vomiting require symptomatic treatment. It is advisable for concussed patients to be kept in quite, low-light environments to avoid exacerbating their symptoms. Suspected fracture, intracranial bleeding or other injury, or focal neurologic deficits should prompt immediate neurosurgical consultation.

CRITICAL INTERVENTIONS

- Determine the need for imaging to identify fracture or intracranial injury.
- Arrange for close follow-up and inform the patient and caregivers about the natural course of concussive symptoms and the need for full cognitive rest.

DISPOSITION

Patients with isolated concussion may be discharged from the ED since they are at minimal risk for developing an intracranial lesion. However, it is important that discharge instructions note the possibility of worsening symptoms or signs consistent with an intracranial process. Repeated vomiting, worsening headache, loss of consciousness, increasing confusion or agitation, seizure activity, vision changes, weakness or numbness, and difficulty walking are symptoms that warrant further evaluation. The CDC has published downloadable documents ideal for use in the ED discharge setting; these can be found at http://www.cdc.gov/concussion/pdf/TBI_Patient_Instructions-a.pdf.

Consensus treatment guidelines recommend initial mental, physical, and emotional rest. Patients should be advised to rest as much as possible, avoid activities that worsen their symptoms, avoid physical activity, and avoid excessive screen time (television, phones, and electronic devices). Consideration should be given to

advising patients to miss school or work as needed while symptoms are present, as often these activities may exacerbate symptoms.

Discharged patients should be advised to follow-up within a week of injury with a provider familiar with the management of concussion. Athletes should be advised not to return to participation in sports until they are cleared by a medical provider. Patients are advised to rest until their symptoms resolve completely without the use of medications. A graded approach to physical activity is then recommended, with activities increased in intensity and duration each day. If symptoms increase during the return to play protocol, patients should return to the previous day's activity level. Return to play *must* be guided by symptoms and not by fixed time spans such as "1 week after injury."

It is estimated that 90% of concussion victims recover within 7 days of their injury (15–17). Concussion symptoms that persist 4 to 6 weeks following the concussive event are characterized as postconcussion syndrome. This syndrome may persist for months to years and can have a profound impact on patients' lives, school, or work schedules. Risk factors at initial presentation have yet to be identified to predict the risk of developing postconcussive syndrome. These patients should be referred to a concussion rehabilitation team, which typically includes medical providers, physical therapist, speech therapists, and occupational therapists trained specifically in concussion management.

Common Pitfalls

- Failing to diagnose a concussion when a patient has a distracting additional injury (e.g., fracture or other injury).
- Dismissing a concussion as "mild" because there are no severe findings on presentation.
- Recommending that an athlete can return to play at a predetermined amount of time (e.g., 1 week after injury) without undergoing further evaluation on follow-up.

CHAPTER 249

Evaluation of the Pediatric Cervical Spine

Jeffrey R. Avner

The developing pediatric cervical spine has numerous features that make it challenging to evaluate. These include unfused synchondroses, incomplete ossification centers, and epiphyseal growth plates. In addition, due to the dynamic changes occurring during bone and ligament development the distribution patterns of fractures and dislocations differ from those of the adult spine. Furthermore, a significant percentage of pediatric spinal cord injuries may occur in the absence of any radiographically identifiable abnormality.

DEVELOPMENTAL ANATOMY

The first cervical vertebra (atlas) develops from three primary ossification centers: the body and two neural arches (Fig. 249.1). The neural arches ossify in utero and fuse posteriorly at approximately the third year of life. The body of C1 is not ossified at birth and does not become visible until approximately 1 year of age. The synchondroses between the body and neural arches (neurocentral synchondroses) fuse at approximately the seventh year of life (1).

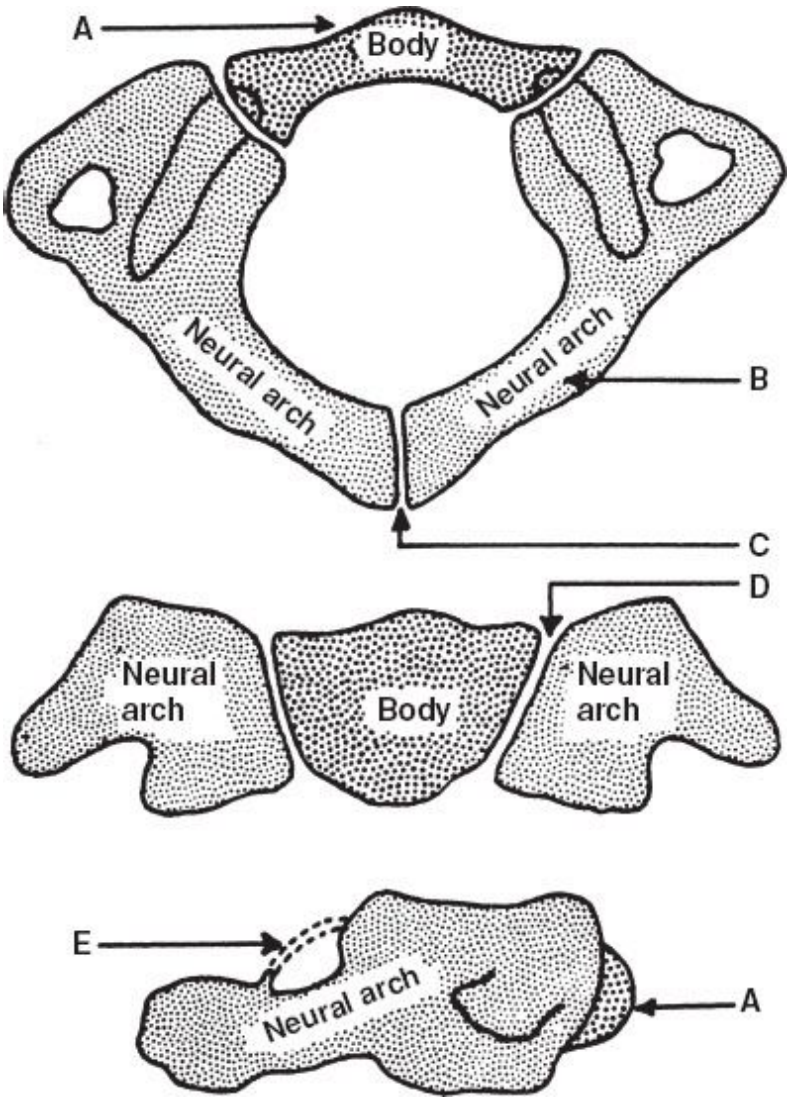

FIGURE 249.1 The first cervical vertebra (atlas). **A:** Body: ossification center becomes visible during first year of life. **B:** Neural arches: ossification center appears in utero at approximately the seventh fetal week. **C:** Synchondrosis of spinal process: fuses at approximately the third year of life. **D:** Synchondrosis about the body (neurocentral synchondrosis: fuses at approximately the seventh year of life). **E:** Ligament surrounding the superior vertebral notch: may ossify later in life. (Reproduced with permission from Fielding JW. Cervical spine injuries in children. In: The Cervical Spine Research Society, eds. *The Cervical Spine*. Philadelphia, PA: JB Lippincott Co.; 1983:268–281.)

The second cervical vertebra (axis) is the most difficult to interpret radiographically because of its four primary ossification centers: the odontoid, body, and the two neural arches (Fig. 249.2). All four ossification centers are visible at birth. A secondary ossification center appears at the apex of the odontoid (summit ossification center) at approximately 3 to 6 years and fuses with the odontoid by the 12th year of life. The synchondroses of the posterior neural arches fuse at approximately the third year. The synchondrosis between the odontoid or body of C2 and the neural arches fuse at approximately the third to sixth year. Before fusion, these synchondroses may be confused with fracture lines. The fusion line of the synchondrosis between the odontoid and the body of C2 commonly remains visible until age 11, and one-third of individuals have a visible fusion line throughout life.

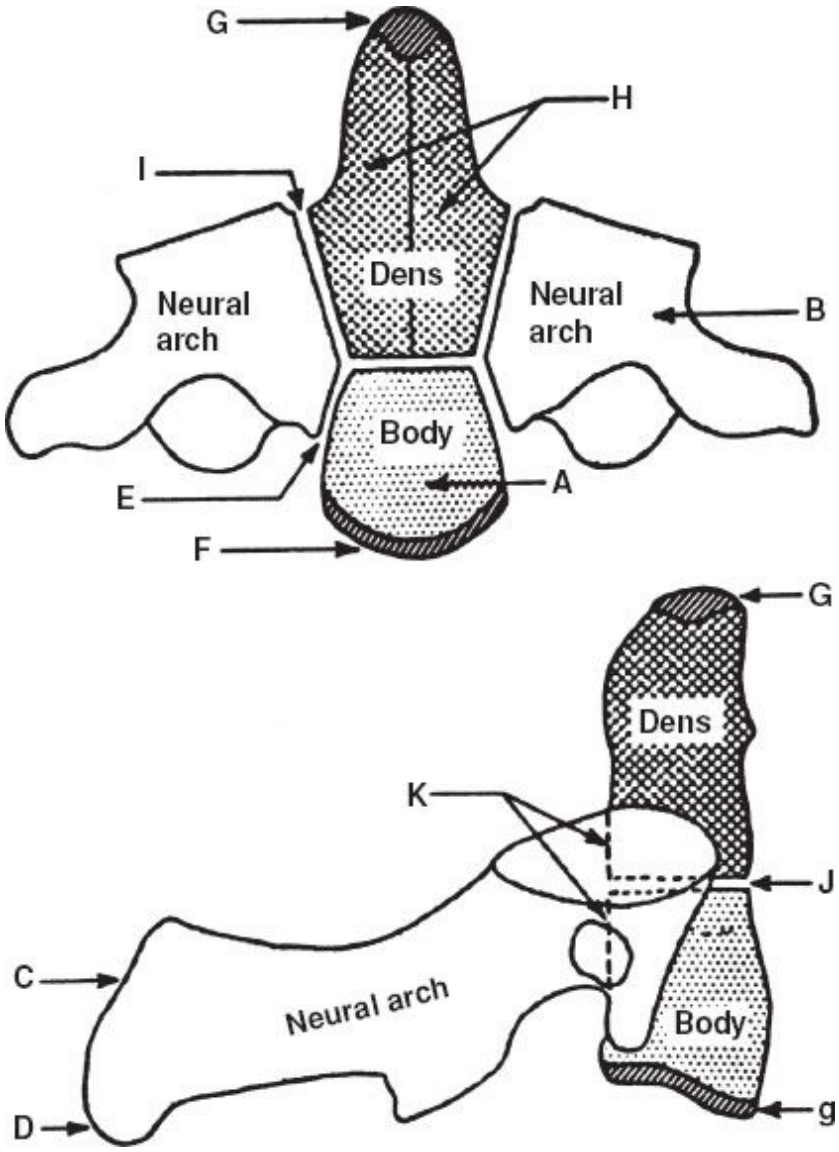

FIGURE 249.2 The second cervical vertebra (axis). **A:** Body: ossification center appears by the fifth fetal month. **B:** Neural arches: appear by the seventh fetal month. **C:** Synchondrosis of spinous process: fuses by the third to sixth year of life. **D,E:** Neurocentral synchondrosis: fuses by the third to sixth year. **F,g:** Inferior epiphyseal ring: appears at puberty and fuses to body at approximately 25 years of life. **G:** Summit ossification center for odontoid: appears at approximately the third to the sixth year and fuses with the odontoid by the twelfth year of life. **H:** Odontoid: develops from two ossification centers that fuse by the seventh fetal month. **J:** Synchondrosis between the odontoid and body: fuses at approximately the third to sixth year of life. (Reproduced with

permission from Fielding JW. Cervical spine injuries in children. In: The Cervical Spine Research Society, eds. *The Cervical Spine*. Philadelphia, PA: JB Lippincott Co; 1983:268–281.)

In the remaining C3 to C7 cervical vertebrae, there are three major ossification centers—the body and two neural arches—all of which are visible at birth (Fig. 249.3). The posterior synchondroses of the neural arches fuse at approximately the third year of life. The neurocentral synchondroses fuse at approximately the third to sixth year of life. Secondary ossification centers appear at puberty along the superior and inferior aspects of the cervical bodies (superior and inferior epiphyseal rings) and at the tips of the spinous processes. Before fusion, these ossification centers may be mistaken for chip fractures of the cervical bodies and clay shoveler's fractures of the spinous processes, respectively. These secondary ossification centers fuse with the main body by age 25. Development of the contiguous ring apophysis encircling the vertebral body surfaces, which occurs up to adolescence, gives the appearance of slight anterior vertebral wedging that must be differentiated from a fracture.

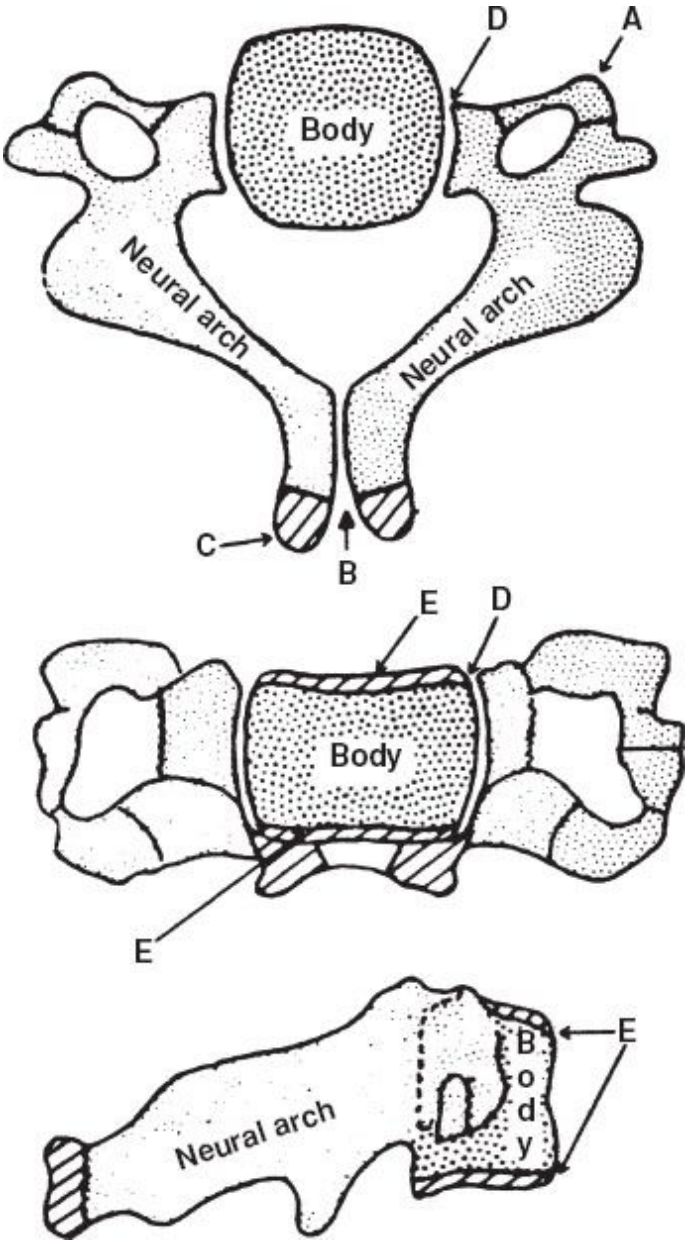

FIGURE 249.3 Typical cervical vertebrae (C3–C7). **A:** Anterior portion of transverse process: may develop from a separate ossification center that fuses by the sixth year. **B:** Synchondrosis between the spinous processes: fuse by third year. **C:** Secondary centers for bifid spinous processes: appear at puberty and fuse by 25 years of life. **D:** Neurocentral synchondrosis: fuses at approximately third to sixth year of life. **E:** Superior and inferior epiphyseal rings: appear at puberty and fuse with body by 25 years of life. (Reproduced with permission from Fielding JW. Cervical spine

injuries in children. In: The Cervical Spine Research Society, eds. *The Cervical Spine. Philadelphia*, PA: JB Lippincott Co.; 1983:268–281.)

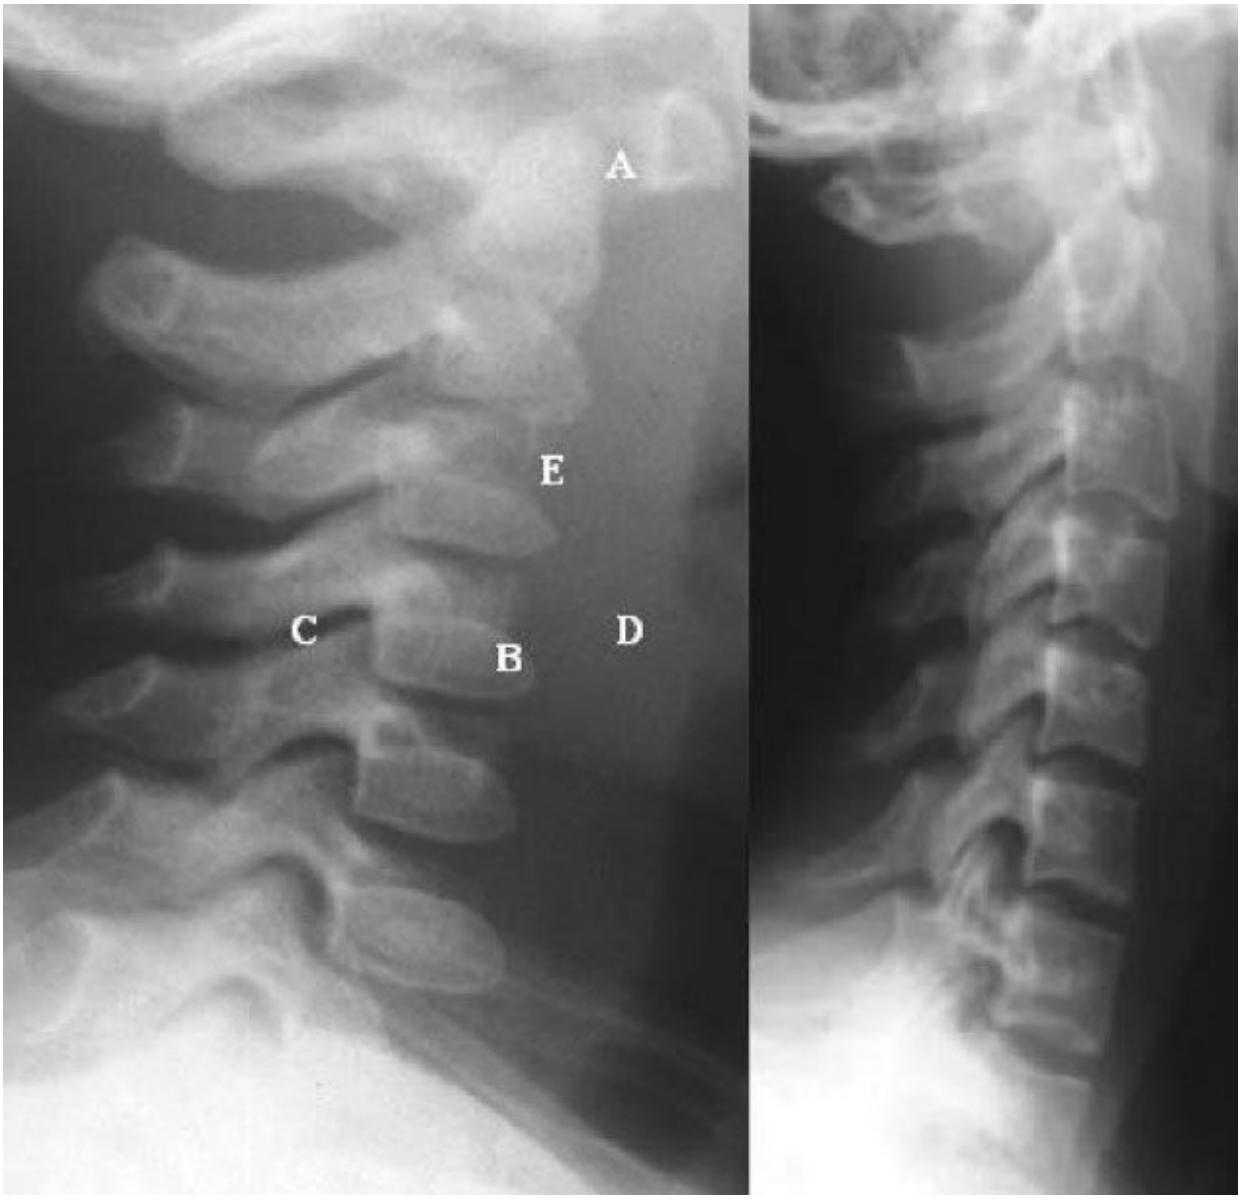

FIGURE 249.4 Comparison of a normal lateral cervical spine x-ray of a child (**left**) and adult (**right**). Normal anatomic differences notable in the pediatric spinal x-ray include **(A)** nonpathologic, widened predental space of 4.5 mm; **(B)** anterior wedging of the vertebral bodies; **(C)** flat interfacet joints; **(D)** increased soft tissue space anterior to the cervical spine; and (**E)** an anterior pseudosubluxation

of C2 on C3. (Reproduced with permission from Yamamoto LG. http://www.hawaii.edu/medicine/pediatrics/pemxray/v5c02.html.)

NORMAL VARIANTS AND CONGENITAL ANOMALIES

The development of the cervical vertebrae during childhood results in a range of normal anatomic and radiologic variants (Fig. 249.4). In particular, the weak support provided by relatively immature neck muscles, elastic interspinous ligaments, and flat interfacet joints create laxity of the vertebrae. In addition, during the ossification process of the immature cervical bodies, an appearance of anterior wedging is produced. Thus, there is more mobility of the vertebral structures in a child compared with an adult whose vertebral alignment is relatively fixed. Owing to this ligamentous laxity, absent lordosis is often a finding on the lateral radiograph in a child with a normal cervical spine, whereas in adults this finding may signify ligamentous injury.

The extreme laxity of ligaments can also exaggerate the vertebral override (pseudosubluxation) of adjacent vertebrae of children younger than 8 years. This finding is most pronounced at the level of C2 to C3 (see Fig. 249.4) but may be also present at C3 to C4. To distinguish pseudosubluxation from true subluxation, Swischuk (2) developed the concept of the posterior cervical line (Fig. 249.5). This line is drawn by connecting the anterior aspects of the spinous processes of C1 and C3. If the anterior aspect of the spinous process of C2 misses this line by 2 mm or more (1.5 mm is borderline), this finding is suggestive of a true subluxation or a hangman's fracture of the neural arches of C2. This posterior cervical line can be applied only in children demonstrating subluxation or pseudosubluxation of C2 on C3. If no subluxation or pseudosubluxation exists, the anterior aspect of the spinous process of C2 commonly misses the posterior cervical line by more than 2 mm.

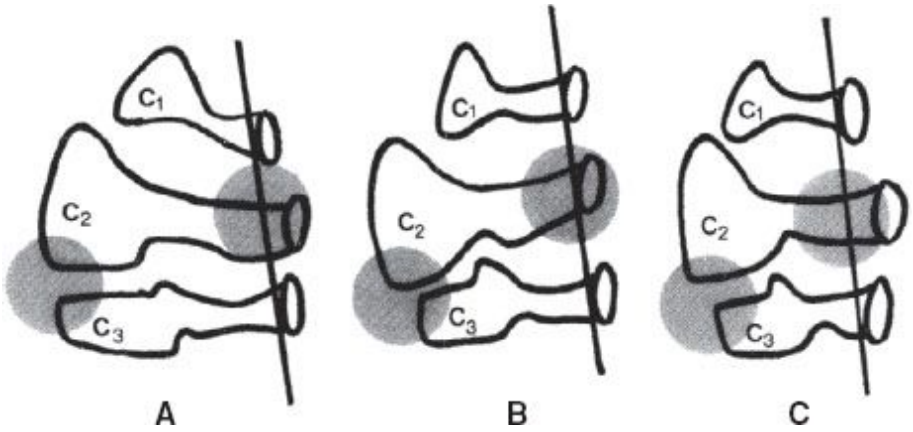

FIGURE 249.5 The posterior cervical line (PCL) is drawn by connecting the anterior aspect of the spinous processes of C1 and C3. The concept of the PCL can be applied only if subluxation or pseudosubluxation is present. **A:** Pseudosubluxation is absent: The anterior aspect of the spinous process of C2 will commonly miss the PCL by 2 mm—*normal* or *abnormal* (PCL cannot be applied). **B:** Pseudosubluxation is present: The anterior aspect of the spinous process of C2 lies on the PCL—*normal.* **C:** Subluxation is present: The anterior aspect of the spinous process of C2 misses the PCL by 2 mm. This finding is suggestive of a hangman's fracture of the neural arches of C2—*abnormal.* (Reproduced with permission from Fesmire FM, Luten RC. The pediatric cervical spine: Developmental anatomy and clinical aspects. *J Emerg Med.* 1989;7:133–142.)

In adults, widening of the predental space (>2.5 to 3 mm) frequently signifies rupture of the transverse ligament resulting in subluxation of C1 on C2. However, in children younger than 8 years, distances of 3 to 4 mm are common. Furthermore, distances up to 5 mm may be seen in nonpathologic instances (2); however, in these cases they should be considered abnormal until proven otherwise.

Widening of the prevertebral soft tissue owing to hemorrhage and edema is an important adult radiographic finding. In children, suggested norms have included soft tissue space <7 mm anterior to C2 or less than three-fourths of the adjacent vertebral body's width. The younger the child, the more unreliable these norms are due to dramatic increases in soft tissue density during expiration or when

the neck is held in mild flexion at the moment any given radiograph is taken.

CLINICAL PRESENTATION

Less than 1% of all spinal cord injuries occur in children younger than 12 years old, about 5% occur in children 12 to 16 years, and nearly 25% occur in 17 to 22 year olds (3). Furthermore, the incidence of pediatric cervical spinal injuries is only 1% to 3%, and only approximately 1% of all pediatric cervical spine radiographs reveal an abnormality (4–6).

The incidence of cervical spine fractures and dislocations increases with age. Radiographically apparent cervical spine injury, excluding birth trauma, is virtually nonexistent in children younger than 16 months (5–7). The cause of cervical spine fractures and dislocations is broad, and the epidemiology of injury may reflect regional differences. In general, motor vehicle accidents and falls account for the majority of injuries in children younger than 8 years old, whereas sports injuries are more common in older children (3,5,7).

Pediatric cervical injuries related to the use of front-passenger airbags have been increasingly described in the literature. Airbag deployment has produced a pattern of cervical injuries in older children traveling in front seats, and crush injuries to the skulls of infants in rear-facing safety seats (8). Thus, a child who is unrestrained or is inappropriately close to an airbag may be at risk of injury. Currently, the American Academy of Pediatrics recommends placing infants and toddlers in a rear-facing car safety seat (CSS) until they are 2 years of age. Children 2 years or older generally should use a forward-facing CSS with a harness for as long as possible, and all children whose weight or height is above the forward-facing limit for their CSS should use a belt-positioning booster seat until the vehicle lap-and-shoulder seat belt fits properly, typically when they have reached 4 feet 9 in in height and are between 8 and 12 years of age. Children younger than 13 years should be restrained in the rear seats of vehicles for optimal protection (9). Unfortunately, critical misuses of car safety restraints have been reported to be as high as 73% (10).

Types of pediatric cervical spine injuries can be divided into those of the upper cervical spine (C1 to C3) and those of the lower cervical spine (C4 to C7). Injuries most commonly seen in the upper cervical spine are fractures or synchondral separations of the odontoid with atlantoaxial dislocations, and hangman's fractures of the neural arches of C2. Abnormalities most frequently encountered in the lower cervical spine are anterior subluxations or dislocations, compression fractures, teardrop fractures, and spinous process fractures. The distribution of the level of cervical spine injury varies with age, reflecting the effect of the relatively large head of the child, coupled with the laxity of ligaments and the nearly horizontal facet joints. Young children have a larger head-to-body ratio that results in higher torques and shear forces being applied to the C1 to C3 regions, increasing their risk for upper cervical spine injuries (5,7,11). As a general rule, children younger than 8 years old have more upper cervical spine injuries, whereas children older than 14 years have more adult-like injury patterns with more low cervical spine lesions. Children between the ages of 8 and 14 are in a transition state between the two. The incidence of neurologic deficits with cervical spine fractures and dislocations also increases with age, with neurologic deficits occurring in 20% of children younger than 8 years of age but in approximately 40% of children aged 8 to 16 years (5).

In addition to vertebral injuries seen on plain x-rays, the pediatric patient may also suffer spinal cord injury without radiographic abnormality (SCIWORA), a term introduced before widespread use of magnetic resonance imaging (MRI). In the child, the flexibility and elasticity of the vertebral column are more than that of the spinal cord. Thus, a distraction injury may cause cord traction or ischemia without noticeable skeletal defects. The pathophysiology of SCIWORA is thought to involve a combination of a diverse multitude of mechanisms, all resulting in a disruption of microvascular blood supply. Proposed mechanisms include spinal cord traction, concussion, hyperextension with inward bulging of the interlaminar ligaments, reversible disc prolapse, flexion compression of the cord, and vertebral artery spasm.

There is wide variability in the reported incidence of SCIWORA, ranging between 18% and 38% of all pediatric spinal injuries (5,12,13). Because of the age-related anatomic differences, it is not surprising that SCIWORA injuries usually occur in younger children (mean age between 9 and 11 years) and involve the upper cervical spine in up to 80% of cases (5,12,13). Interestingly, in one series (12), sports-related activities were associated with 54% of cases of SCIWORA and involved older children and adolescents. Most cases of SCIWORA present with motor or sensory neurologic deficits, most commonly paresthesias, and have partial cord syndromes (5,12,13). However, delayed onset of neurologic deficits and complete cord transection can occur.

The increased mobility of the child's cervical spine also results in specific patterns of injury. For example, the energy of a blunt force tends to be dispersed over more vertebral segments, thereby increasing the incidence of contiguous and even noncontiguous fractures (11,14). Furthermore, the presence of a significant spinal injury implies that a high-energy event occurred; thus, approximately 60% of children with spinal fractures have associated injuries, most commonly thoracic, including pulmonary contusions, pneumothoraces, and rib fractures (11).

ED EVALUATION AND MANAGEMENT

It is often difficult to find appropriately sized cervical collars for infants and young children. Furthermore, improper spinal immobilization may cause neurologic injury, airway obstruction, pain, and increased intracranial pressure. Thus, extreme care must be used when immobilizing a pediatric trauma patient.

It should be noted there are no randomized controlled trials assessing the utility of cervical spine immobilization in trauma patients (15). As a general rule, children who are alert will not move a significantly injured part of the body. When an alert child vigorously resists immobilization, an injury may worsen. Thus, it is acceptable not to immobilize the cervical spine of a young alert child with no obvious injuries who is vigorously resisting medical

personnel. Children with potential cervical spine injury who are not actively resisting treatment however should be immobilized.

Prehospital cervical spine immobilization is best accomplished using a rigid plastic cervical collar and a backboard, combined with tape, sandbags, or a commercially available head-immobilization device. However, neutral position is difficult to achieve and may be present in as few as 11% to 20% of immobilized children presenting to the emergency department (ED) (3,16). The disproportionate head size of young children tends to cause cervical flexion in patients younger than 7 years when immobilized on a standard flat backboard. Flexion can be prevented either by placing padding beneath the back to raise the level of the thoracic spine or by using a spinal backboard with a recess for the occiput. The cervical spine is properly positioned when a line drawn through the external auditory meatus and the anterior aspect of the shoulder is parallel to the backboard.

In the recent past, it was recommended that all children who arrive at the ED with a new neurologic deficit consistent with a spinal cord injury and a history of trauma or concern for suspected trauma should be treated with high-dose methylprednisolone as soon as possible (17). This intervention remains controversial, however. Convincing data to support its use are lacking and there is evidence that high-dose steroids are associated with harmful side effects (18). Therefore, current guidelines do not recommend administration of methylprednisolone for acute spinal cord injury as a standard of care (18,19).

The management of the threatened airway in a child can be an urgent dilemma. Ventilation can frequently be accomplished with a chin-lift alone (which elevates the tongue off the hypopharynx) or in combination with bag-valve-mask ventilation. The jaw thrust maneuver is indicated when there is suspicion of cervical injury. Oral intubation, which is preferred in younger children, is best performed using manual inline stabilization *without* traction so as not to aggravate a distraction injury. Young children require little, if any, extension to visualize the glottis. Nasotracheal intubation should be attempted only in older children with spontaneous respirations.

Cervical spine injuries, although potentially devastating, remain rare. This has led to the development of clinical algorithms that identify children at high risk for cervical spine injury while avoiding unnecessary x-rays (and hence radiation exposure) in low-risk children. A prospective, multicenter study by the National Emergency X-Radiography Utilization Study (NEXUS) group (6) applied the following set of five predictors for low risk of cervical spine injury: (1) no midline cervical tenderness, (2) no focal neurologic deficit, (3) normal level of alertness, (4) absence of intoxication, and (5) no painful distracting injury. Thirty (0.98%) of the 3,065 patients who were younger than 18 years had a cervical spine injury. These clinical criteria correctly identified all cervical spine injury victims (sensitivity of 100%) and correctly designated 603 patients at low risk for cervical spine injury (negative predictive value of 100%). However, the positive predictive value was only 1.2%, and there were only a small number of infants and toddlers included, thus limiting the applicability of NEXUS to this age group.

Several other studies involving children are in broad agreement in supporting a low threshold for radiographic examination of the cervical spine in young children (20). A recent study validated the use of the NEXUS criteria to detect cervical spine injuries in children after trauma and safely allow clearance of the cervical spine by neurosurgical personnel (4). Finally, in a large multicenter study by PECARN of 540 children with cervical spine injury after blunt trauma, 8 clinical predictors of injury were identified: (1) altered mental status, (2) focal neurologic deficits, (3) complaint of neck pain, (4) torticollis, (5) substantial torso injury, (6) predisposing condition, (7) diving, and (8) high-risk motor vehicle crash. Having at least one of these criteria had a sensitivity of 98% and specificity of 26% for cervical spine injury (21).

In light of the existing data, a conservative approach to clearing the cervical spine with clinical criteria in children seems reasonable. If a child is brought to the ED with the neck immobilized but no history of a high-risk mechanism nor direct neck trauma and is awake, alert, cooperative with no distracting injury, has no complaint of neck pain and no neurologic deficit (or history of

transient paralysis or sensory change), the cervical collar can be removed for further neck examination. The child should try to maintain the neck in neutral position (with help from a clinician, if necessary) while the neck is inspected and the spine palpated. If there is no neck tenderness, gentle active range of motion of the neck is allowed. Children with a spinal injury typically limit their neck motion secondary to pain in order to protect the area of injury; therefore, never forcibly extend or flex the child's neck. If there is neck tenderness or limitation of movement due to pain, the cervical collar should be reapplied and appropriate radiographic examination performed. Otherwise, immobilization devices can be removed and the cervical spine cleared clinically.

For patients who cannot be cleared clinically, radiographic examination begins with a lateral cervical spine x-ray with the collar in place. This view, however, may miss 5% to 20% of injuries (2). Therefore, the standard three-view series (lateral, anteroposterior, and odontoid x-rays) should be obtained, recognizing that the open-mouth odontoid view is frequently impossible to obtain in young children. A cervical spine injury may be nevertheless missed because of altered mental status, distracting injury, inadequate examination, or SCIWORA. In addition, a limited appreciation of normal variants seen during growth and development, as well as suboptimal radiographic technique, may also lead to misdiagnosis. In a recent study of 206 children with blunt trauma-related bony or ligamentous cervical spine injury, adequate cervical spine radiographs had a sensitivity of 90% (95% CI: 85% to 94%); among the children with missed injuries, half had either altered mental status or focal neurologic findings (22).

There has been an increase in the use of high-speed computed tomography (CT) scanning to screen test for cervical spine injuries. It has a higher sensitivity (about 98%) for detecting fractures, as well as other injuries potentially missed on plain radiography (4,23,24). Cervical spine CT, however, results in significant exposure to ionizing radiation, which is concerning in children. Also, although CT scanning is preferred for identifying bony injuries, it is less sensitive in detecting ligamentous injuries, which are often seen in

children. In a study of 84 pediatric patients who underwent both CT and MRI studies of the cervical spine after trauma, MRI had a sensitivity of 100% and a specificity of 97% in detecting bony injury (25). Thus, MRI is preferred if there are symptoms of myelopathy or if the patient's mental status makes serial clinical evaluations problematic (24).

In children and young adolescents, the majority of cervical spine injuries occur in the upper cervical spine and are likely to be identified on three-view radiography. Three-view radiography should thus continue to be used for the initial evaluation of the cervical spine in children younger than 14 years, regardless of the child's mental status, given concerns regarding the greater radiation exposure from CT (24). CT scanning should be considered if: (1) adequate plain films cannot be obtained and there is suspicion for injury; (2) there is a fracture, displacement, or other suspicious finding on plain radiograph; or (3) there is high suspicion of injury based on clinical or physical exam findings. As SCIWORA is a real concern in some patients, all children with potential spinal injury should be questioned specifically concerning transient paresthesias at the time of the injury. If the history is positive, a spinal injury should be assumed to be present and immobilization should be maintained until neurosurgical consultation can take place.

KEY TESTING

- Use NEXUS or PECARN criteria, if appropriate, to clinically clear the cervical spine without unnecessary imaging.
- If radiographic clearance is needed, order two- to three-view plain radiographs of the cervical spine (add CT of C1/C2 if intubated).
  - If normal and child is asymptomatic: clear cervical spine.
  - If normal and child is symptomatic: order MRI.
  - If plain radiographs are abnormal or suspicious: order CT and MRI (if bone abnormality); MRI (if no bone abnormality).
- If child is symptomatic, has a neurologic deficit, evidence of SCIWORA, or there is high suspicion of injury based on clinical and physical examination findings: order MRI.

CRITICAL INTERVENTIONS

- Use a properly fitted hard cervical collar to maintain the neck in neutral position.
- If emergent airway management is needed, continue in-line immobilization without traction to avoid creating or exacerbating neurologic injury.
- Order imaging, beginning with a lateral neck x-ray, if the child has any of the following: cervical tenderness or pain, focal neurologic deficit, altered consciousness, intoxication, painful distracting injury, or high-risk mechanism of injury.
- If there is limitation of neck movement, persistent cervical pain, or neurologic symptoms even in the face of unremarkable three-view cervical spine x-rays, maintain immobilization and proceed with additional radiographic studies (e.g., fluoroscopy, CT, or MRI) and neurosurgical consultation.

DISPOSITION

All children suspected of having a cervical spine injury on the basis of clinical findings or radiographic studies should have neurosurgical consultation to assess the severity of injury and need for further evaluation and treatment. Pending further studies, it is prudent to admit all children with suspected cervical spine injury to the hospital. Adolescents with clinically insignificant vertebral injury (e.g., type 1 odontoid fracture, spinous process fracture) and a normal neurologic examination may be considered for outpatient management. Any child with a potentially unstable vertebral fracture or with a spinal column injury without cord damage should be admitted to an inpatient unit. All children with proven spinal cord injury should be admitted or transferred to a pediatric intensive care unit.

Common Pitfalls

- Open synchondroses and secondary ossification centers may be confused with fractures.

- Anterior wedging of cervical bodies, pseudosubluxation of C2/C3 or C3/C4, increased prevertebral soft tissue density, absence of normal lordosis, and widening of the predental space may be normal in pediatric patients.
- A normal radiograph does not definitely rule out spinal cord injury. All children with suspected cervical spine injury should be questioned specifically for transient paresthesias at the time of the injury; approximately half of patients with delayed onset of SCIWORA have this finding.
- A young alert child with no obvious injuries who is vigorously resisting all attempts at immobilization should not be forced into a restraining device, as this may result in secondary injuries.

CHAPTER 250 Thoracic Trauma

Brent R. King

As is the case with adult patients, in children and adolescents trauma to the chest can either be blunt or penetrating, and injures can be restricted to the chest wall or may involve deeper structures.

Blunt trauma causes most injuries in all age groups, although adolescents may be victims of penetrating (1) chest trauma.

Because infants and young children have more compliant rib cages and less well developed thoracic musculature, blunt force to the chest wall is more easily transferred to deeper structures (2). Likewise, given the patient's smaller body mass, missile injuries can be more devastating than might be the case in older patients.

CLINICAL PRESENTATION

Children who have sustained thoracic trauma may present along a spectrum of illness. At one end are those children who appear to have no or very minor injuries and on the other end are those who are critically ill or in extremis. However, because pediatric patients have immature cognitive and verbal skills, emergency physicians must use extra care and rely more heavily upon the results of the physical examination, laboratory, and imaging studies. Additionally, as in the evaluation of any trauma patient, frequent reassessment is required in order to identify evidence of clinical deterioration or occult injuries.

The emergency physician should be alert for signs of intrathoracic injuries, including tachypnea, tachycardia, abnormal movement of the chest wall, and diminished or abnormal breath sounds. Less

specific signs such as hypotension and tachycardia are associated with significant injuries, including vascular injuries within the thoracic cavity (3). External signs of trauma like “seat-belt marks” and other bruises may indicate trauma to internal organs and should prompt further investigation. As is the case with adult patients, older children and adolescents who are conscious should be directly questioned and examined for the presence of chest wall pain or tenderness.

DIFFERENTIAL DIAGNOSIS

Blunt Chest Trauma

Blunt trauma, the most common mechanism of chest injury in the pediatric age group may cause injury to the chest wall musculature and ribs, as well as injury to the lungs, heart, great vessels, or diaphragm. Trauma involving both the chest and abdomen is more common than isolated thoracic trauma, making evaluation for the presence of associated intra-abdominal injuries mandatory.

Significant bruising of the chest wall, complaints of pleuritic chest pain, local tenderness to palpation, an unusual respiratory pattern, or abnormal excursion of the chest wall, all suggest rib fracture. Traditional wisdom has long held rib fractures uncommon in pediatric patients, but recent studies suggest that they are more common than was previously suspected (3,4). Rib fractures in very young children carry two important implications. First, rib fractures, especially lateral rib fractures in babies, are often associated with child abuse (fractures occur when the child’s chest wall is squeezed or compressed by an adult) (5); and second, due to the more compliant pediatric chest wall, rib fractures may indicate that there has been a significant blunt force and the patient may have sustained pulmonary, cardiac, or intrathoracic vascular injuries.

Abnormal or absent breath sounds suggest a pulmonary contusion, pneumothorax, or a hemothorax caused by intrathoracic vascular injury (3). Tachycardia and hypotension in the presence of unilaterally decreased breath sounds suggest tension pneumothorax. This injury can also be associated with other signs of elevated

intrathoracic pressure (e.g., distended neck veins). Tension pneumothorax is a life-threatening emergency requiring prompt treatment with a needle or tube thoracostomy.

On the other hand, tachycardia and hypotension in the presence of normal breath sounds imply injury to the heart or to vascular structures within the mediastinum; pericardial tamponade is the most common injury associated with these symptoms. In rare cases, direct blunt trauma to the heart can cause cardiac contusion, with potential subsequent cardiac dysrrhythmias. Commodio cordis represents a specific direct blunt injury to the heart itself that causes immediate ventricular fibrillation and cardiac arrest. It occurs most commonly among young males after a direct blow to the precordial chest region (e.g., a thrown baseball or elbow to the chest) (6).

Finally, it must be remembered that the esophagus travels through the mediastinum, so injures to mediastinal structures can also injure the esophagus. The esophagus can also be directly injured by forceful emesis, as a result of an attempted Heimlich maneuver, or when certain objects or substances are swallowed.

Penetrating Trauma

The differential diagnosis of penetrating chest injury is necessarily broad and depends on the mechanism of injury and its location. Projectile weapons, especially firearms, deliver significant force at the point of impact and beyond and can injure organs that are remote from the point where the projectile entered the body. Projectiles can be deflected by bones or other structures, and knives or other devices can lacerate tissues deeper than originally suspected upon examination of the blade. Therefore, it is safest to assume a patient with penetrating trauma has sustained injuries to multiple intrathoracic structures until evaluation proves otherwise. All of the injuries described in the section on blunt trauma can also occur as a result of penetrating trauma. Some injuries, however, like pericardial tamponade or injuries to mediastinal structures are more common after penetrating trauma (7).

ED EVALUATION

The evaluation of the child with blunt or penetrating chest trauma begins with a process familiar to most emergency physicians (8). After a patent airway is assured, the patient's chest is auscultated to note respiratory effort and the presence or absence of normal breath sounds in both hemithoraces. While normal bilateral breath sounds do not mean that no significant injury has occurred, they do suggest that the patient can tolerate a brief period of evaluation to determine the nature and location of specific injuries. Children who do not have adequate respiratory effort require immediate assisted ventilation, followed by placement of an artificial airway. Those who are hypoxemic but have a reasonably normal respiratory effort can be managed with supplemental oxygen, pending further investigation.

The patient's circulatory status is then addressed and life threats identified and treated. Hypotension in the presence of unilaterally decreased breath sounds implies the presence of a tension pneumothorax or a massive hemothorax. Tension pneumothorax can be associated with air hunger and decreased oxygen saturation. Hypotension is an inconsistent finding, and distended neck veins, while frequently discussed, may be present but are uncommonly found (9). Resonance with percussion of the chest wall might also be noted. On the other hand, because hemothorax is associated with significant blood loss, hypotension tends to dominate the clinical picture, but signs of respiratory distress are typically also present (9). The neck veins may not be distended and the large amount of blood in the chest cavity can result in dullness to percussion. Both findings require urgent intervention. Tension pneumothorax can be managed by immediate placement of a thoracostomy tube or can be temporarily converted to an open pneumothorax by needle thoracostomy. In younger, smaller patients, this procedure can be performed by placement of an over-the-needle plastic catheter in the second intercostal space in the mid-clavicular line or in the fourth interspace in the mid-axillary line. In larger adolescents, the mid-

axillary line is preferred as it avoids the musculature of the chest wall. Longer catheters may be required in obese children.

Massive hemothorax should be managed by tube thoracostomy and by transfusion to maintain circulatory function. In the past, emphasis was placed on autotransfusion of the blood evacuated from the thoracic cavity, but recent research has called this practice into question and it is currently considered controversial (10). Patients who have significant blood draining from the thoracostomy tube are candidates for urgent operative intervention.

Open pneumothorax is another potentially life-threatening injury. Also known as a “sucking chest wound,” this injury prevents the establishment of negative intrathoracic pressure during inspiration and renders effective respiration impossible. It can be definitively treated with placement of a tube thoracostomy and closure of the chest wall defect. In the emergency department (ED), however, it is sometimes treated by placement of an occlusive dressing over the wound which is left open on one side, creating a “flutter valve” that allows air to exit the thoracic cavity during expiration but prevents air from entering during inspiration.

Victims of trauma who have signs of life during transport but become moribund within minutes of arrival at a trauma center are potential candidates for ED thoracostomy. The indications for performing ED thoracostomy in children are identical to those in adult patients. Trauma centers that care for children should have available appropriate equipment to perform this procedure.

After the primary survey is complete and the patient is stabilized, a secondary survey should be performed. The secondary survey of the chest includes a careful external examination of the anterior, posterior, and lateral aspects of the chest to identify signs of injury, auscultation of the chest in several areas, and palpation of the soft tissues and bony structures of the chest wall. Any positive findings can then be used to guide further diagnostic testing.

Pneumothorax may be suspected on the basis of decreased breath sounds or the presence of air in subcutaneous tissues. Often, however, it is identified on routine chest imaging. Since pneumothorax can be difficult to detect by clinical examination,

most victims of significant blunt chest trauma and all victims of penetrating trauma must undergo routine chest radiography unless a near-immediate chest CT is being performed (1). Recently, the FAST examination (focused abdominal sonography in trauma) has become the E-FAST examination (extended FAST) with the addition of ultrasound evaluation of the upper lung fields. The absence of the normal finding of the pleural linings moving against one another (so-called lung slide or lung sliding) is indicative of pneumothorax (11). Computed tomography (CT) of the head, chest, abdomen, and pelvis in victims of major trauma has made it possible to identify virtually every significant injury, and many insignificant injuries, in a matter of minutes. CT allows the detection of even the smallest pneumothorax. However, this enhanced imaging capability comes at the price of a substantial dose of radiation. A small percentage of patients who undergo comprehensive CT scanning will later develop one of a variety of cancers as a result of this radiation exposure (see Chapter 245). As children have longer life expectancies than older patients and therefore a longer period after exposure to radiation, they are thought to be at greater risk. Consequently, many authorities recommend more judicious use of CT scanning in the pediatric population (12).

Pulmonary contusion is a common injury that is caused by a direct blow transmitted to the lung, resulting in hemorrhage, interstitial edema, alveolar collapse, and consolidation (3,13). Although evidence of chest wall injury may be minimal or absent, a pulmonary contusion should be suspected when there is history of a likely mechanism and the presence of hypoxemia or rib fracture (1,3). Pulmonary contusion may not be visualized on the initial chest x-ray, but may be visible on subsequent films, usually within 6 hours of the injury. The radiographic appearance is that of an opacified lung segment (13). If a patient has unexplained respiratory distress after blunt trauma, a CT may be indicated since it is more sensitive than plain films for identification of pulmonary contusion (13).

Hemothorax is usually the result of injury to an intrathoracic blood vessel or to the lung tissue itself. Hemothorax is suspected

when the patient has deceased breath sounds, evidence of hypovolemia, respiratory compromise, or dullness to percussion on the affected side (8,9). External evidence of injury to the chest wall should also raise clinical suspicion. In many cases, however, hemothorax will be identified on routine chest radiograph or will be seen when the diaphragm is visualized on E-FAST scanning. Most hemothoraces require evacuation with a thoracostomy tube. In the past, authorities have advocated the use of large-bore tubes to insure adequate drainage, but more recent literature suggests that this is not as important as was once thought (14). Persistent drainage of blood from the chest tube ($>$100 mL/hr or $>$20% of the child's blood volume) is an indication for surgical intervention.

Direct injury to the heart and mediastinal structures can occur with either blunt or penetrating trauma. Missile injuries or stab wounds in any part of the thorax can involve the heart and much of the chest and abdomen as well. Blunt trauma to the anterior chest can also involve the heart and the great vessels. Bruising and tenderness of the anterior chest wall, distant or muffled heart sounds, especially when accompanied by unexplained hypotension, or diminished pulses should all raise suspicion for an injury to the heart (8). Although some cardiac injuries (e.g., pericardial effusion) might be suspected based upon the findings of a routine chest x-ray, the test of choice for the urgent evaluation of the heart is bedside ultrasonography. The four-chamber subxyphoid (sometimes called "subcostal") view of the heart is a routine part of the E-FAST examination. This study can quickly identify the presence of a pericardial effusion with or without tamponade physiology and also allows for the rapid assessment of cardiac activity and the adequacy of ventricular function. Pericardial tamponade, which can be identified by the presence of right ventricular diastolic collapse on ultrasound, is a life-threatening emergency that requires urgent operative intervention or the performance of bedside emergency pericardiocentesis (15).

Cardiac contusion is a much rarer condition that can occur as a result of a forceful, direct blow to the anterior chest. Patients with myocardial contusion may present with dysrhythmias, unexplained

hypotension, or elevation of cardiac-specific enzymes (8,16). Two-dimensional echocardiography is essential for inspection of the valves, the pericardial space, and ventricular wall motion (1,16). Treatment of children with serious myocardial contusion should follow the same guidelines as for acute myocardial infarction in adults (16). In most cases, injuries are not serious and management is usually supportive, including continuous monitoring for rhythm disturbance and hypotension (1,16).

Injury to other mediastinal structures, most notably the aorta and the esophagus, are uncommon in children and adolescents but can occur as a result of significant blunt trauma or penetrating injuries. Signs of aortic injury include paraplegia, upper extremity hypertension, diminished pulses in the lower extremities, or hypotension. A widened mediastinum, sternal fracture, or first-rib fracture may be noted on plain chest x-ray (1). Victims of significant blunt and penetrating trauma will, however, very often undergo CT scanning of their chests. Contrast-enhanced CT identifies almost all significant aortic injuries.

KEY TESTING

- Plain chest radiography for most patients
- Bedside ultrasound to identify the presence of pneumothorax or pericardial tamponade in patients with hypotension, decreased or abnormal breath sounds, muffled heart sounds, or cardiac arrhythmias
- Electrocardiogram performed and cardiac enzymes measured in patients with arrhythmias after blunt chest trauma
- CT should be considered in patients suspected of having significant intrathoracic injuries and should be considered the test of choice for suspected thoracic aortic injury
- Patients with significant blood loss and those requiring large-volume transfusion should have a prompt type and cross match for blood products and should have their coagulation parameters measured

ED MANAGEMENT

The ED management of children and adolescents who are victims of chest trauma largely depends upon the findings identified during the initial clinical evaluation and testing. Some patients will be found to have sustained only minor injuries and can be treated with analgesia and local wound care. Other patients will require near-immediate transfer to the operating room for life-saving interventions. However, many patients will require some intervention or observation by the emergency physician. Patients with life-threatening injuries resulting in respiratory compromise, tension pneumothorax, massive hemothorax, or pericardial tamponade require urgent management as previously described. Hypoxemic patients should receive supplemental oxygen but the routine administration of oxygen to all patients has recently been discouraged (17). Likewise, patients with hypotension should receive fluid resuscitation and, if needed, blood and blood products (8,18). Fluid administration is not a substitute for identification and treatment of injuries, however, nor is it appropriate for hemodynamically stable children.

Rarely, patients with blunt chest trauma may have potentially dangerous dysrhythmias which require antidysrhythmic agents or electrical cardioversion.

As previously noted, ED thoracostomy is only likely to be effective if it is performed in a setting where appropriate resources are available for definitive management of the patient's injuries, and then only in selected patients.

Patients with isolated penetrating injuries, such as stab wounds, will require initial evaluation by chest x-ray, ultrasound, or CT. In the absence of pneumothorax or other significant injury, older patients can be observed for a period of 4 to 6 hours. If they remain clinically stable during observation and repeat chest imaging fails to identify the presence of a pneumothorax or other injury, they can often be discharged from the ED with precautions or transferred to an observation setting for continued monitoring (19). Younger children should most often be placed in an observation setting or

admitted to the hospital after such injuries, and especially so if the mechanism is unclear or if abuse is suspected.

Patients with pneumothorax require one of three types of treatment. Those with minor pneumothorax may be initially managed with inspiration of 100% oxygen and observation, without placement of a thoracostomy tube. In some cases no other treatment is needed. Those with larger pneumothorax who are clinically stable may be good candidates for the placement of a small-bore thoracostomy tube attached to a Heimlich valve. The Heimlich valve allows gas from the chest cavity to exit but does not allow gas from the external environment to re-enter the chest. These devices offer several advantages. They are smaller and can be placed over a guide wire with less discomfort than might be experienced during the placement of a thoracostomy tube. They leave a much smaller scar, which may be important for cosmetic purposes. Stable patients can ambulate with the device in place. Finally, if suction is deemed to be necessary for complete evacuation of the pneumothorax, these catheters can accommodate standard thoracostomy suction devices (20). Many patients will not be appropriate candidates for either observation or placement of a Heimlich valve, and should be treated with an appropriate thoracostomy tube.

Pulmonary contusions should be addressed with great caution. Hypoxemic patients should receive supplemental oxygen in the ED. More importantly, however, the emergency physician should recognize that although a pulmonary contusion might appear relatively minor on initial presentation, these injuries can evolve over time and eventuate in respiratory compromise. Thus, most, if not all, of these patients should be admitted to a monitoring setting (1,4,13).

CRITICAL INTERVENTIONS

- Prompt recognition of the physiologically stable versus physiologically unstable patient.
- In patients with inadequate respiratory effort or who are hypoxemic despite the administration of supplemental oxygen,

establish an artificial airway and insure adequate ventilation and oxygenation.
- Immediately treat tension pneumothorax with a needle or tube thoracostomy.
- In patients suspected of having a pneumothorax or pericardial tamponade perform a bedside ultrasound to evaluate the pleura and the pericardium.
- For patients with massive hemothorax and other causes of intrathoracic hemorrhage, employ balanced resuscitation using blood component therapy after one or two initial boluses of crystalloids.

DISPOSITION

Just as the nature and extent of the patient's injuries dictate her or his ED management, these factors also determine the appropriate disposition. Children who have been found to have not been injured or to have sustained only minor injuries can be safely discharged with the usual caveat that they must remain under the care of reliable adults who can bring them back for further attention should they have an unexpected change in their condition.

Many injured children not require operative or other intervention but have findings that warrant admission to an inpatient unit or an observation setting. Examples include children with minor pneumothorax or pulmonary contusion. Adolescents with fractures of one or two ribs (except those with fractures of the first, second, or third rib) may be safely discharged in the absence of other findings, but patients with multiple rib fractures warrant observation. Rib fractures in younger children suggest that significant blunt trauma was delivered to the chest wall. Such patients should usually be placed in an observation setting or admitted to the hospital. Patients with a flail chest should be admitted to an intensive care unit for close monitoring. Likewise, all children whose injuries are more serious or whose condition has the potential to become worse should be admitted to a monitored setting.

Children with ongoing hemorrhage and those with serious pulmonary, cardiac, diaphragmatic, or mediastinal injuries may require operative intervention and if so, should be taken directly to the operating room or admitted to an intensive care unit pending surgery.

In many cases, an injured child requires resources that are not available at the treating facility. Such children should be transferred to a pediatric trauma center. Ideally, such transfers should occur once the patient has been stabilized, but even if it is not possible to completely stabilize the patient, the benefits of transfer often outweigh the risks. Once the referring center has reached the limits of its capability, transfer is in the patient's best interest (8). When available, a dedicated pediatric transport team should be deployed to effect the transfer in a timely fashion. Referring physicians should also consider consultation with specialists at the trauma center (via telephone or telemedicine link) prior to transfer.

One special population of children bears mention. When the emergency physician suspects that a child's injuries have been intentionally inflicted or are the result of caretaker neglect, he or she has a duty to report these suspicions to the appropriate authorities and should not discharge the patient until cleared to do so.

Common Pitfalls

- Failure to recognize that chest injury in children may occur with little or no external findings.
- Failure to understand that seemingly minor pulmonary contusions can worsen over time, leading to significant respiratory compromise.
- Failure to promptly recognize hemodynamic instability in children.
- Failure to recognize evidence of child abuse.

CHAPTER 251

Abdominal Trauma

Christine E. Koerner

Abdominal trauma is a leading cause of morbidity and mortality in children (1–5). The poorly developed abdominal musculature of young children, as well as their more compliant thoracic cage, places them at risk for abdominal injuries (3,4,6). The majority of these injuries are caused by blunt trauma (80% to 90%) (2,5–7), with motor vehicle accidents (as passenger, pedestrian, or bicyclist) and falls as leading causes (1,4–7). Penetrating injuries are rare (10% to 20%) in infants and young children (2,6) but appear to be more prominent among adolescents (6,8).

CLINICAL PRESENTATION

Children who have sustained abdominal trauma may have clinical findings on a spectrum from little or no evidence of serious injury to obvious life-threatening injuries. In most cases, however, patients can be divided into two broad categories, those with evidence of physiologic compromise and those with no evidence of physiologic compromise (5,6). This distinction is important because those patients in the former category will require resuscitation prior to or concurrent with their diagnostic evaluation, whereas those in the latter group require diagnostic evaluation only (5,6). It is important, however, to recognize that patients can move up and down the spectrum of illness during their emergency department (ED) evaluation and that frequent reassessment is mandatory to avoid missing clinical deterioration (1,6).

Attention to the physical examination can provide clues to potential injuries. Initially, vital signs should be obtained, as a child with tachycardia, tachypnea, and hypotension may have significant intra-abdominal injuries (3). Patients who have incurred abdominal trauma may have external injuries such as bruises, tenderness, and distension (1,3,6,7). Abdominal distension may be a sign of hemoperitoneum, but it is also a common nonspecific later finding in the crying child with aerophagia (5). Some injuries such as concomitant femur fractures, as well as those patients with a Glasgow coma scale less than 13, are associated with intra-abdominal injury (4,9), However, abdominal injury may not always be immediately apparent. This is typically the case for children with altered sensorium, neurologic impairment, or painful distracting injuries (4).

DIFFERENTIAL DIAGNOSIS

Given that many vital organs are located in the abdomen, trauma, whether blunt or penetrating, often injures more than one organ (1,2,5,6,8). This fact necessarily makes the differential diagnosis broad. However, in many cases, the patient's clinical presentation allows the practitioner to focus on a few key diagnoses (5). For example the child who presents with hypotension after a blunt abdominal injury has, in all probability, an injury of the liver or spleen (1,5). It is also important to recognize injury patterns that suggest the diagnosis of "seat belt syndrome" (see below) (6,10,11) as these patients have a threefold risk of intra-abdominal trauma as well as a 13-fold increase in the risk of gastrointestinal injury (11). In addition, abdominal trauma secondary to child abuse (6) should always be suspected in cases where the history is inconsistent with the mechanism of injury (6).

Though it is appropriate to use initial clinical findings to narrow the differential diagnosis and focus the patient's evaluation, care must be taken not to prematurely exclude certain diagnoses (6). In many cases, early symptoms of injury may be subtle and only

diagnosed after a thorough initial assessment followed by continual reassessments (6,9,12).

ED EVALUATION

Early ED evaluation follows a pathway familiar to most emergency practitioners (5–7). The evaluation begins with an assessment of the airway, followed if necessary by definitive airway management. The second step is the evaluation of the adequacy and effectiveness of respiratory efforts. The patient with hypoxemia should receive supplemental oxygen, whereas respiratory failure should be treated with mechanical ventilation.

Once the patient is assured of a stable airway and adequate respirations, attention is directed to the evaluation of the circulatory system (5,6). Victims of blunt trauma with hemodynamic compromise are evaluated differently from those without physiologic abnormalities (1,5,13–15). Though both groups undergo an initial physical examination intended to identify areas of tenderness, guarding, and signs of peritoneal irritation, patients in the former group require urgent resuscitation and an urgent evaluation to identify intra-abdominal pathology as soon as possible (5,6).

Currently, the preferred first imaging study is the Focused Assessment with Sonography for Trauma (FAST) examination. The FAST examination is an ultrasound scan performed at the bedside, often during the resuscitation phase of care. The FAST examination is intended to identify fluid (blood) in the peritoneal cavity. A minimum of four sonographic views are used. The right and left upper quadrant scans are used to identify fluid in Morison pouch and the splenorenal recess. A suprapubic view is used to find fluid collected behind the bladder. Finally, the subxiphoid view helps to exclude nonabdominal causes of hypotension by evaluating the heart and the pericardium. If the FAST examination reveals intra-abdominal fluid in an unstable child, immediate surgery is usually indicated (5,7,16). If the FAST examination is unavailable or is negative in a patient with hemodynamic compromise who has no

other source for his or her symptoms, then a diagnostic peritoneal lavage (DPL) should be considered (6). If a DPL is necessary it should be performed by the surgeon caring for the child, as DPL may interfere with subsequent abdominal examinations or imaging on which the decision to operate may be based (1). However, neither DPL nor FAST can identify the source of bleeding, and the decision for surgical intervention in the unstable patient should not depend on these studies (5,6). Although the FAST examination has modest sensitivity when used alone to identify hemoperitoneum or intra-abdominal injury in children with blunt abdominal trauma, it is most useful in combination with both the physical examination and laboratory tests (16,17).

Further evaluation of the hemodynamically unstable patient should include laboratory values for hemoglobin and blood type and crossmatch (5). Other laboratory studies such as amylase for diagnosing pancreatic and small-bowel injury and transaminase levels as markers for hepatic injury (5–7) are more controversial. In females of childbearing age, a blood or urine specimen should be sent for a pregnancy test. Urine should also be sent for urinalysis and a drug screen, if indicated (1,6).

The child with blunt abdominal trauma who is hemodynamically normal may be evaluated somewhat less aggressively. In recent years, contrast-enhanced computed tomography (CT) has become the study of choice in the evaluation of victims of blunt trauma with abnormal abdominal examinations and in those whose examinations are unreliable because of an altered sensorium, poorly developed verbal skills, or the presence of distracting injuries (1,4–6). The identification of intra-abdominal injuries by CT in the hemodynamically stable child permits for nonoperative management by the surgeon (1).

However, CT is not without risks, as fatal cancers are predicted to occur in the future in approximately 1 in 1,000 children who have undergone CT (6). Therefore, CT should only be performed when medically necessary and when the results will change management. Criteria such as the Blunt Abdominal Trauma in Children (BATiC) score (negative predictive value of 97%) are available to predict

patient's at low risk for abdominal trauma. The BATiC score predicts the absence of abdominal organ injury from blunt abdominal trauma utilizing abdominal Doppler ultrasound, physical findings, (abdominal pain, hemodynamic instability, peritoneal irritation) and blood tests. If the score is ≤ 7, intra-abdominal lesions are not probable and a CT scan or hospital admission may be preventable (18).

The utility of baseline laboratory values in the hemodynamically stable patient is also controversial. Capraro et al. retrospectively reviewed the use of routine laboratory studies (complete blood count, chemistry, coagulation studies, liver function tests, and pancreas enzymes) as a screening tool in trauma and found that none had sufficient sensitivity (range 5% to 75%) or negative predictive value (range 63% to 75%) to rule out intra-abdominal injury (11). If the abdominal examination is normal but the history is still worrisome, a reasonable diagnostic approach includes obtaining a hemoglobin, alanine aminotransferase (AST), aspirate aminotransferase (ALT), and urinalysis; laboratory tests are most helpful when combined with other physical examination and diagnostic test studies rather than in isolation (4,7,8). It is, however, recommended that children suspected of being physically abused be screened more liberally with transaminases to identify occult abdominal injury (8).

Penetrating abdominal injuries are rare, and their precise incidence is unknown. These injuries always necessitate evaluation by a surgeon (6). It is important to note that thoracic gunshot wounds and any penetrating injury below the nipples anteriorly and the scapula posteriorly may also involve the diaphragm and the abdominal cavity (2,4,8). Hemodynamically stable patients with penetrating trauma and suspected thoracoabdominal injury should receive an upright chest roentgenogram to exclude an associated hemothorax or pneumothorax and to document the presence of peritoneal air (6). Using clips to mark all entrance and exit wounds, the stable patient with a gunshot wound should also undergo a supine abdominal x-ray to assist in identification of the missile track and the presence of retroperitoneal air (6). However, the

hypotensive unstable child with penetrating abdominal trauma requires prompt operative treatment, and there should be no screening radiographs in the ED if a surgeon is available (6,8). Likewise, if the patient is hemodynamically stable with penetrating injury and has microscopic or gross hematuria, further evaluation for urologic injury is indicated.

KEY TESTING

- CBC
- Blood type and crossmatch
- Transaminases in appropriate circumstances
- Urinalysis
- Urine pregnancy test in females of childbearing age

ED MANAGEMENT

All patients with abdominal injury should undergo resuscitation according to established guidelines (1,5,6). Prompt consultation of a surgeon is indicated if intra-abdominal injury is suspected (6). After a functional airway is established, one should assess breathing.

Patients with hemodynamic instability should receive a 20-mL/kg bolus of normal saline or Ringer lactate, administered rapidly via intravenous or intraosseous access (1,5,6). Nasogastric tubes (NGTs) and urinary drainage catheters (Foley) may be placed, while blood is obtained for hemoglobin and hematocrit and type and crossmatch (3,5). An NGT should not be placed if there is visible blood or cerebrospinal fluid in the nose, significant facial injury, or a basilar skull fracture (6). Foley catheters should be avoided when blood is seen at the urethral meatus, there is a perineal or scrotal hematoma, or there is a high-riding prostate (6).

If a child remains hemodynamically unstable after 40 mL/kg of crystalloid fluid, then 10 to 20 mL/kg or more of blood should be transfused and continued efforts made to identify the source of bleeding (5,6). After intrathoracic or central nervous system causes for the hemodynamic instability are excluded, abdominal sources of bleeding should be sought. A FAST examination or DPL is performed

to determine the presence of intraperitoneal blood and, if positive, necessitates a laparotomy (5,6). Other indications for surgical exploration in the hemodynamically unstable child include abnormal vital signs, transfusion needs exceeding 40 mL/kg, peritoneal signs, abdominal distension, hypovolemia, and base deficit. It is important to note that abdominal distension secondary to aerophagia can mimic an acute abdomen, and insertion of a NGT can decompress the stomach (5). Intravenous antibiotics, analgesics, and tetanus toxoid should be administered as indicated (6).

In contrast, management of patients who present with abdominal trauma but are hemodynamically stable depends on the injuries identified and investigations planned. Children who are hemodynamically stable with suspected abdominal injury should have a hemoglobin, transaminases, (AST, ALT) and urinalysis (3). Females of childbearing age should undergo a pregnancy test (6). Other laboratory values and radiographic studies are performed for specific indications (6). Although an IV hep-lock may be placed, NGTs and Foley catheters are not routinely placed.

CT is the diagnostic study of choice for evaluating stable patients with suspected blunt abdominal trauma, as most blunt solid organ (liver, kidney, spleen, and pancreas) injury in children can be successfully managed nonoperatively (4–6,11). Observation should be carried out in hospitals equipped and staffed to care for children with these injuries (4,6). Therefore, once the workup is complete, the patient should be admitted to the hospital or transferred to a facility capable of the required monitoring and of managing his or her injuries. In most cases, a surgeon should be involved in the patient's care (6). Patients should receive serial abdominal examination and hemoglobin levels (5,6). Children with hemoglobin that remains >7 mg/dL can be treated conservatively without blood transfusion. Indications for surgical exploration based on CT imaging are evidence of bowel injury, renovascular injury, bladder rupture, ureteral transection, pancreatic injury, and contrast extravasations (4,6).

Children with penetrating wounds of the abdomen require surgical consultation, as children are more likely to require surgical

intervention for these injuries than adults (2,6).

Penetrating wounds of the abdomen and associated hypotension, peritonitis, evisceration, or ongoing hemorrhage require operative intervention (6). Pneumoperitoneum, unexplained fever, or leukocytoses are additional indications for laparotomy. Children with abdominal gunshot wounds require mandatory surgical exploration (6), and hemodynamically unstable children with stab wounds also require surgery (2,6,8). However, children with anterior stab wounds who are asymptomatic may be managed expectantly by pediatric and trauma surgeons (2,6).

SPECIFIC INJURIES

Diaphragm

Diaphragmatic injuries caused by blunt or penetrating thoracoabdominal trauma are rare in children (13), and there is no gold standard for early diagnosis. Chest x-rays in patients with diaphragmatic injury may show an irregular contour of the hemidiaphragm, but this finding is present in $<50\%$ of patients (6). Diagnostic tools such as ultrasound and CT scan are not always accurate (13), and the diagnosis may be missed initially (13). Surgical repair remains the standard of care for these patients (13).

Spleen and Liver

The spleen and liver are the most commonly injured abdominal organs in children (5,11). A history of left-sided trauma and physical findings of left upper quadrant tenderness, left shoulder pain (Kehr sign), and anemia may accompany splenic injury, but in some cases physical findings are initially subtle (5). Stable children with hepatic injuries usually complain of right upper quadrant pain and/or right shoulder pain. In addition, elevated transaminases are often noted (4,5). Liver injuries in children are generally more severe than splenic injuries and are associated with a higher morbidity and mortality.

The CT can accurately identify and grade both splenic and hepatic injury (5,7), and a surgeon can manage many of these injuries

nonoperatively if the patient remains hemodynamically stable. Splenic injuries that require <40 mL/kg of blood (one-half blood volume) in the first 24 hours (5,6) typically do not require operative intervention. Liver injuries tend to rebleed, and a lower transfusion cutoff of ≤ 30 mL/kg in the first 24 hours is more indicative of the need for surgery.

Intestinal Perforation

Intestinal perforations are atypical in children unless associated with seat belt syndrome (5,10,12). The diagnosis is often not made until peritonitis occurs, and surgical intervention is always required. Complications occur often with duodenal injuries (20% overall), and mortality increases from 11% to 40% with operative delay of greater than 24 hours. Twenty percent of cases of duodenal injury are associated with pancreatic damage (10). If there is no clear mechanism of injury for the intestinal perforation, then child abuse should be suspected (5).

Kidney

Renal injuries are commonly seen in children after blunt abdominal trauma, but the majority can be managed nonoperatively (6,14). Hemodynamically stable children with gross hematuria, microscopic hematuria (≤ 50 RBCs/HPF), or a history of rapid deceleration injury should be evaluated with CT (1,14,19). Stable patients with isolated microscopic hematuria (<50 RBCs/HPF) and suspected renal contusion may be observed without initial radiographic imaging but should be followed with serial urinalyses and bed rest.

Pancreas

Pancreatic injuries are uncommon (5,20) and there is no consensus regarding the management of patients with blunt pancreatic injuries (15). Serum amylase levels, lipase levels, and abdominal CT can be useful in making the diagnosis, although an early normal serum amylase does not rule out major pancreatic injury (5). Likewise, the

CT scan may not be accurate in determining the location and type of injury (5,20). Patients with distal transection of the pancreas require operative management (5,15), and patients with pancreatic contusion but no major ductal injury can be managed nonoperatively (5). When there is uncertainty regarding the status of the main pancreatic duct, patients should undergo further testing with endoscopic retrograde cholangiopancreatography (ERCP), or magnetic resonance cholangiopancreatography (MRCP) (15).

Pelvis

Pelvic fractures are uncommon in children (21,22), and they are more likely to be present in patients with multiple injuries and high injury severity scores (5,21). Contrary to adult findings, pelvic fractures in children usually do not cause massive bleeding, and only a small number of patients have associated genitourinary tract injuries (5). In the past, the pelvic x-ray was routinely used to establish the diagnosis (5,6,21,22), although in most cases the physical examination alone is reliable. (5,21,22). Clinical predictors of pelvic fracture in children include the presence of pelvic contusions or abrasions, hip or pelvic pain, abdominal pain or distension, and femoral deformity or pain. These predictors can help to determine the need for a pelvic x-ray in children with Glasgow Coma scale 13 to 14 and a history of blunt abdominal trauma (21,22). The majority of pelvic fractures in children are stable ring fractures, and treatment tends to be nonoperative, with most being treated with bed rest.

Seat Belt Syndrome

Also called the *lap belt complex,* the seat belt syndrome consists of characteristic patterns of visible abdominal wall or hip ecchymosis, intra-abdominal injury, and lumbar spine injuries that result from compression, burst, or shearing which are associated with wearing a lap-type seat belt. The seat belt sign (contusion) may be found on the abdomen and hips (3,10,16), and small-bowel perforation may be present even when the abdominal CT scan is negative (5,6,10).

Thus, patients with a seat belt sign should be admitted for serial abdominal examinations (5,10).

Lumbosacral injuries (i.e., compression) and Chance fractures may also occur in patients with a seat belt sign and small-bowel perforation. Chance fractures are caused by hyperflexion over the fulcrum of the seatbelt (1,5,6,10,16), which results in bony and ligamentous injuries (3). Plain radiographs are the diagnostic study of choice (5), and treatment includes hyperextension in cast or brace for bony injuries and spinal fusion for ligamentous injuries. Such injuries should be considered in children with other signs of the seat belt syndrome.

Likewise, solid organ laceration or contusion may also occur (kidney, spleen, liver, pancreas, or bladder) in restrained children, and a high level of suspicion is needed (10).

CRITICAL INTERVENTIONS

- Management of the physiologically stable versus physiologically unstable patient (Table 251.1).

TABLE 251.1
Management of the Physiologically Unstable Versus Physiologically Stable Patient

Physiologically Unstable Patient with Abdominal Trauma	Physiologically Stable Patient with Abdominal Trauma
Airway	**Airway**
100% oxygen; evaluate the necessity for an ET tube or needle thoracostomy	100% oxygen initially
Fluids	**Fluids**
20 mL/kg NS or Ringer lactate via bolus	IV hep-lock may be placed
Repeat bolus one or two times if needed	
Transfuse 10–20 mL/kg of blood for ↓ BP	
If vital signs are unstable, repeat the blood transfusion and proceed to laparotomy	
Laboratory Studies	**Laboratory Studies**

Operating room or the ICU	Admit solid organ injuries; abdominal pain; and a small subset of anterior stab wounds in asymptomatic patients

Hb, hemoglobin; HCT, hematocrit.

- Administer 20 mL/kg NS or Ringer lactate by bolus and repeat one or two times if needed in the unstable patient with

abdominal trauma.
- Transfuse 10 to 20 mL/kg of blood for unstable patients who have received two or three boluses of NS or Ringer lactate and continue to have low blood pressure.
- Perform a FAST examination to check for intra-abdominal bleeding in the unstable patient with abdominal trauma.
- Early consultation of pediatric trauma specialists for children with suspected intra-abdominal injury

DISPOSITION

The patient's clinical assessment, the injury severity, and diagnostic results must be considered (1,4,16) when deciding on the necessity of surgical consultation. However, a surgeon familiar with pediatric trauma should be contacted as early as possible if intra-abdominal injury is suspected (2,3,6–8). All children with penetrating injury should be evaluated by a surgeon because of the likelihood of exploratory surgery (1). Depending on the type of injury, other specialists may also be needed for consultation (1).

The majority of children with abdominal trauma are admitted to the hospital for observation. The determination of which hospital unit is most appropriate for the care of these children depends on the severity of the injury and the type of monitoring required. For example, most children with splenic and hepatic injuries are admitted to the ICU for observation, serial examination, and management. All patients with seat belt sign, even with a negative CT scan, should be admitted for observation (12).

When considering the disposition of patients with abdominal trauma, one should keep in mind that there are no laboratory tests that reliably diagnose solid or visceral injury. Intestinal injuries can be especially difficult to diagnose (22). Thus, all children with persistent abdominal tenderness on examination, a seat belt sign, laboratory abnormalities, or radiographic evidence of intra-abdominal organ injury must be admitted for monitoring. Patients with a major solid organ injury should be admitted to an area

capable of providing intensive monitoring or transferred to an appropriate facility.

A small group of children with minimal abdominal pain and a history of abdominal trauma may be discharged home if they appear well and no significant injuries have been detected after a complete ED evaluation. In most cases, these patients should be observed in the ED for a few hours and then reexamined. After discharge, they should have follow-up with their primary care physician.

In a multicenter study of children evaluated in EDs after blunt abdominal trauma Kerry et al. (23) concluded that intra-abdominal injuries were rarely diagnosed after a normal abdominal CT scan result. The authors concluded that a normal physical examination and a normal abdominal CT may not require routine hospitalization for children after blunt abdominal injury. Safe discharge home is possible when there is no other reason for admission (16,23).

All patients admitted for observation of abdominal injuries should be managed in concert with pediatric or trauma surgical specialists (6). If a patient with abdominal injuries arrives at a hospital not equipped to care for children or the type of injury the patient has, then the patient should be rapidly stabilized and transferred to a regional pediatric or general trauma center (6). Patients with a pediatric trauma score of ≤ 8, or a revised trauma score < 12, should be transferred to a designated trauma facility (15). Similarly, children with multiple rib fractures at risk for splenic and liver injury may require transfer to a specialized center, as these injuries should be managed by surgeons familiar with nonoperative solid organ injury in facilities equipped to handle sequelae promptly (6).

Common Pitfalls

- Failure to promptly recognize hemodynamic instability in children.
- Failure to identify rupture of the small-bowel in seat belt syndrome.
- Failure to recognize evidence of child abuse.
- Failure to recognize that crying may cause abdominal distention.

• Failure to consult a pediatric surgeon or trauma specialist early.

CHAPTER 252 Pediatric Fractures

Robert L. Cloutier

Fractures account for 15% of all pediatric ED visits. It has been reported that 42% of boys and 27% of girls will have at least one fracture by age 16. Fractures result from recreation, falls, sports, motor vehicle accidents, abuse, or other causes. It is important for ED physicians to recognize pediatric fracture patterns, be able to properly describe fractures, understand which fractures need orthopedic consultation in the ED, and provide proper disposition.

Children's fractures, in the context of a growing skeleton, differ from those in adults for a number of anatomic and physiologic reasons. The most obvious is the presence of the physis, or "growth plate," by which longitudinal bone growth occurs. The physis divides the young bone into four distinct zones: Epiphysis ("upon the physis"), physis (growth plate), metaphysis ("next to the physis"), and diaphysis ("between the physes"). The growing skeleton is more porous, which allows for greater flexibility and deformation before a fracture occurs. Pediatric bone is also contains more radiolucent cartilage than in adults, which is an important consideration when interpreting radiographs. Attachments such as ligaments and tendons are often stronger than the bone itself, making fractures about the physis more common than sprains or dislocations. The thick, active periosteum in children allows fractures to remodel and heal quickly, so proper alignment and reduction are essential to prevent progressive deformity.

DIFFERENTIAL DIAGNOSIS

The pattern of a fracture may reveal the mechanism of injury, which is important when determining whether a fracture pattern is consistent with the history. *Spiral* fractures are produced by a twisting mechanism. *Oblique* fractures occur with overloading in a longitudinal plane. *Transverse* fractures occur as a result of linear forces applied across the longitudinal axis of a bone, resulting in angulation. *Butterfly* fractures occur when both a longitudinal and linear force are applied to the same bone; these fractures are intrinsically unstable.

Torus or *buckle* fractures are a common type of pediatric fracture, particularly of the radius. These fractures occur when the cortex buckles secondary to an applied compression force. These fractures are stable and there are any complications. *Bowing* fractures, or *plastic deformations,* occur when longitudinal forces cause persistent bowing or deformation of a bone without any radiographically visible change to the cortex or periosteum. This injury requires reduction, and most commonly appears in the ulna or fibula. *Greenstick* fractures occur near the metaphyseal–diaphyseal junction when, because of the plasticity of children's bones, there is just enough force to start a fracture but not enough to cause it to extend across both cortices. Greenstick deformities are the most common fracture pattern seen in children. *Avulsion* fractures usually occur in adolescents around the pelvis, tibial tubercle, or phalanges after a strong muscular contraction when the ligaments and tendons are stronger than the adjacent bone.

The Salter and Harris (SH) classification scheme for physeal fractures is widely used. In an SH type I fracture, the fracture extends only through the physis. This type of injury may not be evident on radiographs because of minimal displacement, but the diagnosis can be made clinically when there is tenderness over the physis and adjacent soft tissue swelling. The SH type II fracture is one that extends from the physis into the metaphysis and is the most common physeal fracture seen in children (Fig. 252.1). In type III, the fracture extends from the physis into the epiphysis and the joint. This fracture tends to occur when the physes begin to partially close in mid- to late adolescence. SH type IV fractures cross the epiphysis

and the physis, exit through the metaphysis. The type IV is also intra-articular and most commonly appears in the lateral condyle of the humerus or in the tibia. The SH type V fracture describes a physeal injury that results from a crushing and compressive force and can often result in growth arrest. Initial radiographs may be normal, and the diagnosis is usually made in follow-up after the onset of growth arrest.

FIGURE 252.1 A Salter–Harris II fracture of the ring finger proximal phalange. The fracture extends along the physis and exits across the metaphysis. Closed reduction and splinting are appropriate for this fracture.

Understanding how to describe fractures when communicating with orthopedic colleagues is an important skill and can help to ensure optimal patient care. The radiographs should be described

using anatomic terms such as proximal, distal, diaphysis, metaphysis, and physis. Specific details should include the fracture pattern (e.g., spiral, oblique, greenstick), amount of displacement, degree of angulation, and description of any shortening or malrotation. Displacement is measured by using a percentage relative to the width of the bony shaft. Hairline fractures are described as nondisplaced, and anything less than 10% is considered minimally displaced. Angulation is described by using the direction of the apex and the degree of angulation (e.g., the Colles fracture has a dorsally displaced hand but is best described as having a certain degree of volar angulation). Physeal fractures should be described using the SH I to IV classification. Importantly, the presence of neurovascular compromise or of an open wound or a puncture wound must be communicated to the consultant.

ED EVALUATION

The diagnosis and initial management of pediatric fractures are very important because callous formation starts within a week. It is important to establish the circumstances and the mechanism surrounding the injury. Developing rapport while taking the history also allows the physician to gain the trust of the child and hopefully obtain a better examination.

The physical examination cannot be overemphasized, and it can be improved with adequate pain control. The examination should always start with an assessment of the neurologic and vascular status distal to the injury. Most children will cooperate with a light-touch sensory and limited motor examination. Next, the injured limb should be completely exposed by removing any splints or clothing and then exposing the uninjured limb for comparison. The injured extremity should be inspected closely for point tenderness, soft tissue swelling, or breaks in the skin. Radiographs are necessary for areas of significant swelling or tenderness, and breaks in the skin suggest the possibility of an open fracture. Surrounding joints should be examined through a gentle range of motion, looking for pain or possible dislocation.

High-quality radiographs are imperative; accepting poor radiographs can result in misdiagnosis or a missed fracture. Radiographs should include at least two views (anteroposterior and lateral) made at a 90-degree angle to one another. Injuries near a joint (e.g., wrist, elbow, knee, and ankle) frequently require an oblique, or third, view. Additional radiographs of the joint above and below the injury should be considered. To get the highest-quality films with the least amount of patient discomfort, it is important to address pain control before sending the patient to radiology.

Unique aspects of the interpretation of pediatric radiographs are the various stages of bone development and physeal closure. When there is a question regarding a fracture versus normal developmental anatomy, resources such as oblique views, a radiology textbook of normals, or comparison views of the uninjured extremity can be extremely helpful. Computed tomography (CT) scans can occasionally be useful when evaluating complex fractures and are often used to evaluate spinal injuries. Overall, stress-view radiographs have fallen out of favor. Finally, there are very few indications in the ED for modalities such as magnetic resonance imaging, arthrography, arteriography, or bone scanning.

Compartment syndrome is rare, but may occur following forearm and lower leg injuries (Fig. 252.2). The typical history is of a fracture or crush injury followed by bleeding and swelling within the inelastic adjacent fascial compartments. The earliest signs are pain out of proportion to the injury and extreme pain with passive range of motion. Findings such as pallor, paresthesias, and pulselessness are all late manifestations. Compartment syndrome is a true limb-threatening orthopedic emergency. Immediate consultation with an orthopedist is warranted to measure compartment syndromes and to consider emergency fasciotomy.

FIGURE 252.2 A tibia and fibula fracture resulting from high-energy trauma. This fracture is at an increased risk for compartment syndrome and should be followed up closely.

KEY TESTING

- Proper radiographs including two views (anteroposterior and lateral) made at a 90-degree angle to one another. Strongly consider x-rays of a joint above and below the injury.

ED MANAGEMENT

Once a fracture has been diagnosed, the emergency physician has three options: Immobilization with outpatient referral to a specialist; orthopedic consultation in the ED; or provision of definitive fracture care. The first option is the most common choice and should be considered for nondisplaced or minimally displaced fractures with a

low risk of short-term complications. In contrast, ED consultation by an orthopedist is necessary if there is any suggestion of compartment syndrome or neurovascular compromise, and urgent consultation should also be strongly considered for any open, moderately displaced, intra-articular, or unsuccessfully reduced fracture. Detailed follow-up care instructions should also be provided to every fracture patient.

The goal of immobilization is to maintain the fracture in a reduced position, prevent further injury, and improve patient comfort. Splinting is the most common form of immobilization utilized in the ED, and splints are available in plaster, in padded fiberglass, and in premade form. The benefit of plaster is the ease of molding, but plaster requires padding and special attention to the bony prominences. The benefit of fiberglass with prepadding is the ease of application, but these are more difficult to mold. Premade commercial splints are quick, but improper fits may result in poor immobilization. Proper splints should immobilize the fractured bone completely, which may require extending the splint to joints above and below the fracture. It is important to document neurovascular status *both* before and after splint application. The keys to splinting are adequate padding, a proper mold, and over-wrapping.

Casts are less commonly used in the ED because of concerns about progressive swelling inside a rigid cast. This concern may be alleviated to some degree by splitting the cast. Proper cast application requires skill and the right balance between being tight enough for immobilization and loose enough to allow for swelling. In most emergency settings, a properly applied splint is more appropriate, is safer, and is easier to apply.

Operative management should be considered for any unstable fracture. Operative management is the mainstay for SH III and IV fractures, malaligned intra-articular fractures, fractures with high risk for neurovascular compromise, and open fractures.

TREATMENT OF SPECIFIC FRACTURES

Shoulder

Fractures of the clavicle are common; 80% involve the middle third. They can be managed effectively with either a sling or a figure-of-eight brace for 3 to 4 weeks. Slings appear to be more commonly used. When pain allows, gentle range of motion exercises should be encouraged, but activity restrictions continue for at least 6 weeks following the injury. The rare indication for orthopedic intervention in the ED is when there is skin tenting or posterior displacement of the medial portion of the bone. Skin tenting can lead to local necrosis and the delayed creation of an open fracture. Medial clavicle fractures with posterior displacement pose a risk to mediastinal structures and should be imaged with CT scanning before attempts at reduction.

Fractures of the proximal humerus respond well to immobilization using a sling or shoulder immobilizer for 4 weeks. Most proximal humerus fractures are SH I or II fractures and, given the tremendous remodeling capabilities of the proximal humerus, heal well even with moderate displacement and angulation.

The scapula is rarely fractured, but it can be expected to heal with a sling or shoulder immobilizer. Exceptions are scapular fractures associated with clavicle fractures or with extension into the glenoid. These two situations require orthopedic consultation. A scapular fracture represents a high-energy injury and should trigger a careful history and evaluation for associated injuries.

Elbow

Pediatric elbow injuries are challenging. Proper radiographs must include both a true lateral and an AP view because these fractures may be subtle. Lateral radiographs should be carefully inspected for three specific findings that help in the diagnosis of occult elbow fractures. The first is the “sail sign,” which is seen when either the anterior or posterior fat pads is elevated because of hemarthrosis after a fracture. The second is the anterior humeral line, which should bisect the middle third of the capitellum when there is no fracture. The third is the alignment of the radial head and the capitellum, which should form a straight line extending along the

axis of the radius and passing through the center of the capitellum. Oblique or comparison views should be considered if clinical suspicion persists.

Occult fractures and nondisplaced supracondylar fractures can be managed with a posterior splint and close follow-up with orthopedics. Displaced supracondylar fractures are usually managed with operative pinning. The majority of lateral condyle fractures, medial condyle fractures, and radial neck fractures with more than 30 degrees of angulation are also managed operatively because of the need to maintain anatomic reduction. Fractures around the elbow are at high risk for neurovascular injury.

Forearm

Fractures of the radius and ulna are very common in pediatrics. The majority do very well with closed reduction and immobilization. It is important to also examine the elbow and wrist because associated injuries can be overlooked (e.g., Monteggia fractures are proximal ulna fractures with radial head dislocation, and distal torus fractures of the ulna are associated with physeal radial fractures). Torus or "buckle" fractures of the radius are managed with immobilization in a splint or cast for 3 to 4 weeks. Most reductions of single- or two-bone forearm fractures can be successfully performed with procedural sedation, but close follow-up is mandatory since reductions can drift into progressive deformities.

Hand and Wrist

Fractures of the pediatric hand remodel much better than those in adults. The vast majority of phalangeal fractures can be managed nonoperatively with splinting. The preferred position for immobilizing interphalangeal joints is in extension. Before splinting, closely inspect each digit for malrotation by looking at the alignment of the nail bed in extension and its orientation toward the scaphoid in flexion. Malrotation deformities will not remodel well and require reduction or operative attention. Metacarpal fractures, such as the "boxer's fracture" of the fifth metacarpal, are much more

common in adolescents and athletes who take part in contact sports. Metacarpal fractures tolerate significant angulation and are usually managed nonoperatively with immobilization (flexion of the metacarpophalangeal joint is preferred). Thumb fractures are managed by closed reduction and immobilization with a thumb spica. Tenderness in the snuffbox region suggests a scaphoid fracture and requires special scaphoid views in addition to the routine AP and lateral radiographs. Scaphoid fractures are difficult to diagnose in the ED, so when this is suspected, the patient should be placed in a thumb spica splint and have close follow-up arranged. Special attention should be paid to crush injuries of the hand and nailbed injuries with underlying phalangeal fractures.

Hip and Pelvis

Hip and pelvis fractures are relatively rare in children and usually occur as part of high-energy trauma or in sports-related avulsions. High-energy trauma is associated with pelvic fractures, acetabular fractures, and fractures of the proximal femur. These require orthopedic intervention as well as management of associated nonorthopedic injuries. It is important to determine whether the fracture is stable or unstable. Pelvic fractures can be accompanied by hemodynamic instability, gastrointestinal injury, or genitourinary injury. Slipped capital femoral epiphysis (SCFE) can mimic proximal femur fracture on radiographs, but a good history differentiates SCFE from high-energy trauma. Avulsion fractures of the hip and pelvis occur in adolescents when one of the hip muscles suddenly contracts, causing avulsion of the connected bone. Avulsions usually heal with pain control and protected weight bearing for 3 to 4 weeks. All pelvic and hip injuries need an AP radiograph of the pelvis. The standard lateral view is a frog-leg, but a cross-table lateral is preferred when there is concern about displacing a fracture with external rotation of the hip.

Knee

Fractures of the young knee commonly involve the distal femoral physis. The proximal tibia and the patella are less commonly fractured in children. Sports injuries in adolescents can result in avulsion fractures of the tibial plateau or the tibial tubercle. Standard radiographs of the knee include an AP, lateral, and patellar view (Merchant or sunrise view). The hip needs to be closely evaluated with any apparent knee injury because of the frequent occurrence of referred pain from hip pathology. Most physeal fractures of the knee do well with closed reduction and long-leg immobilization, but intra-articular fractures require surgical reduction and fixation. Patellar fractures and avulsion fractures can be managed with straight-leg immobilization and nonweight bearing until follow-up.

Leg

Fractures along the shaft of the femur and tibia require orthopedic consultation. Femoral fractures are managed on the basis of age and fracture characteristics, but either traction, spica casting, external fixation, or internal fixation can be expected. Tibial fractures with angulation or displacement require closed or open reduction, depending on the severity. Nondisplaced tibial and fibular fractures can be managed with long-leg immobilization, nonweight bearing, and close orthopedic follow-up. Importantly, tibial fractures are at increased risk for compartment syndrome and for progressive deformities.

A *toddler's fracture* is an oblique, nondisplaced, distal tibia fracture occurring in children up to 4 to 6 years of age. Toddler's fractures often present to the ED with limping after rather minor trauma or an unwitnessed event. Physical examination signs are subtle, and oblique views may be helpful. Patients with suspected toddler's fracture should receive long-leg immobilization and orthopedic follow-up because radiographs and the physical examination may be unremarkable in the ED.

Ankle

Younger children are more likely to experience physeal fractures than sprains after ankle injuries. SH I fractures of the distal fibula may occur after inversion injuries; radiographs are often negative except for soft tissue swelling, yet the clinical examination reveals tenderness over the physis. SH I and II fractures of the fibula are treated with short-leg immobilization, and reduction if necessary. SH II fractures of the tibia result from much greater forces and require reduction with long-leg immobilization. Fracture patterns in the ankle begin to change once the growth plates start to close in adolescence. SH III fractures of the tibia are known as Tillaux fractures (Fig. 252.3). They occur when the medial tibial physis closes before the lateral portion, and the strong tibiofibular ligament avulses the lateral epiphysis with a strong external rotational force. The triplane fracture is classified as a SH IV fracture that occurs during adolescence. It is unique because the fracture exists in three planes: Sagittal, transverse, and coronal. Triplane fractures require a CT scan to determine the degree of bony displacement. Triplane and Tillaux fractures both require orthopedic consultation, and most eventually undergo surgical fixation.

FIGURE 252.3 A classic Salter–Harris III fracture of the distal tibia called the "Tillaux." The fracture extends along the physis, across the epiphysis, and into the intra-articular space. This is an intra-articular fracture and requires orthopedic consultation and surgical fixation.

Foot

Most fractures of the foot involve the phalanges or the metatarsals and can be managed with short-leg immobilization or a hard-sole shoe (insert or postop shoe). Fractures of the fifth metatarsal, first metatarsal, and great toe need special attention to ensure maintenance of the foot borders. If one of these requires reduction, short-leg immobilization without weight bearing should follow. Pain at the base of the second metatarsal should alert the clinician to the possibility of a tarsometatarsal dislocation known as a *Lisfranc injury*. Calcaneal fractures are often the result of a fall from a

significant height and should prompt radiographs of the spine to look for associated compression fractures. Complex foot fractures require CT in addition to AP, lateral, and oblique radiographs.

Child Abuse and Nonaccidental Trauma

Child abuse is a major pediatric concern and should be considered with any fracture (see Chapter 290). Twenty-five to 50% of abused children have a fracture, and 10% of all injuries in children younger than 2 years are nonaccidental. Specific fractures such as transphyseal distal humerus fractures, spiral fractures, and "corner" or "bucket-handle" fractures are frequently mentioned as classic for child abuse, but the most common nonaccidental fracture is the routine transverse fracture. Suspicious histories inconsistent with the fracture pattern, or any fracture in a child younger than 2 years, should raise concerns about abuse. It is important to inquire about the mechanism and history of the injury. A suspicion of nonaccidental trauma demands a skeletal survey, and physicians are required by law to notify social services. Suspected cases of abuse must be admitted to the hospital to ensure patient safety and to allow for further investigation.

Open Fractures

Open fractures are treated in the ED with intravenous antibiotics, wound irrigation, and tetanus prophylaxis as needed. Most open fractures are taken to the operating room for irrigation, debridement, and fixation within 6 to 8 hours of injury. Lawnmower injuries are responsible for a large number of open hand and foot injuries in children.

CRITICAL INTERVENTIONS

- Obtain emergent consultation for signs of compartment syndrome or neurovascular compromise.
- Inspect injuries closely for evidence of a puncture or open wound.

- Recognize high-risk fractures—callous formation is rapid and a missed fracture may result in later deformity.
- Immobilize all fractures securely for protection and healing.

DISPOSITION

Discharge instructions can be referred to by the family long after they have left the ED, and thus should not be overlooked. Many fracture care discharge instructions can be incorporated into a standardized form that can be modified as necessary. Routine information about cast and splint care should be included, along with emphasis on the importance of ice and elevation. Specific instructions about follow-up care within 5 to 7 days, and a detailed list of problems warranting return to the ED (e.g., increased pain, discoloration, or sensory changes), is absolutely necessary. It is important to remember that young patients need analgesic medications, and specific instructions on their use should be provided.

When a child is being transferred or referred for definitive care, it is crucial to avoid immobilizing the injury in a position that tents the skin. Tenting can progress to necrosis or an open fracture in just a few hours. Inflatable splints should also be avoided because they can put external pressure on tissue that is already traumatized.

Common Pitfalls

- Failure to obtain high-quality radiographs; at least two to three radiographic views are required.
- Failure to provide early and adequate analgesia; pain control is crucial before radiographs and physical examination and upon discharge.
- Failure to consider child abuse when there is a suspicious history.

ACKNOWLEDGMENT

The author gratefully acknowledges the contributions of Greg Canty to the content of this chapter.

CHAPTER 253 Pediatric Sports Injuries

Robert L. Cloutier

Despite our nation's obesity epidemic, the number of children participating in sports has continued to climb, and pediatric athletes frequently present to the emergency department (ED) after an injury. More than 20% of pediatric injury-related visits involve a sports-related injury. More than 30 million, or half, of all children and adolescents participate in organized sports, and many others participate in unorganized sports such as skateboarding and bicycling. The most common sports injuries evaluated in the ED are fractures, dislocations, sprains, strains, head injuries, contusions, and lacerations. ED physicians also need to be familiar with sports-specific injuries such as avulsion fractures, overuse syndromes, and brachial plexus injuries. The presentations are rarely life-threatening, but the conditions can result in chronic morbidity if not recognized and treated properly.

Overall the most common sports injuries are fractures and dislocations. Fractures may involve the diaphysis, metaphysis, or physis. Fractures surrounding the physis are common since the adjacent physis itself, not its surrounding ligamentous structure, is the weakest component. As a result, physeal fractures occur when forces are transmitted across the joint from the stronger ligaments to the weaker areas of physeal bone. This is in contrast to similar injuries in adults where sprains occur because weaker ligaments tear while pulling on stronger, mature bone. Most physeal fractures seen in sports are classified as Salter–Harris I or II. However, once the physis begins to close during adolescence, unique patterns such as the Salter–Harris III and IV fractures emerge. The adolescent suffers

more ligamentous sprains, similar to adults, because of the maturing skeleton. It is helpful to remember the adage that "the younger the child, the more likely a sports injury will result in a fracture."

Dislocations are common in adolescent athletes, but are very rare in athletes younger than 10 to 12 years. The most frequent dislocations associated with sports involve the proximal interphalangeal (PIP) joints of the hand. PIP dislocations occur when the fingertip is hyperextended during contact sports or when catching a ball. Other common dislocations involve the patella and the glenohumeral joint of the shoulder. Patella dislocations occur with a twisting mechanism on a partially flexed knee, and they are almost always lateral dislocations. Glenohumeral shoulder dislocations occur with contact sports such as wrestling and football when forces are applied to an abducted, externally rotated arm. Ninety percent of glenohumeral dislocations are anterior.

Avulsion injuries occur when stronger muscle tendons adhere to weaker areas of bone called *secondary ossification centers* or *apophyses.* When a strong muscular contraction occurs, the tendon may pull the bony apophysis away from the larger bone. As the force of muscular contraction increases in adolescence, these injuries increase in number. The most common site for avulsion injuries is the pelvis, where the iliac crest, anterior inferior iliac spine, anterior superior iliac spine, or the ischium can be avulsed. Another example is the tibial spine (or eminence) avulsion resulting from hyperextension of the knee. The tibial tubercle, greater trochanter, lesser trochanter, and phalanges may also be avulsed.

Overuse injuries are increasing in children with the advent of year-round training and overtraining. Overuse injuries come in many varieties and often present to the ED because of an acute exacerbation of chronic pain, such as in a stress fracture. The most common stress fractures involve the proximal to middle third of the tibia, but the metatarsals, femur, and humerus may also be affected. Spondylolysis is a stress fracture through the pars interarticularis of the vertebrae, and is common in young athletes with lumbar back pain. Little League shoulder is a Salter–Harris I injury of the proximal humerus in overhand-throwing athletes such as baseball

pitchers; Little League elbow is a constellation of elbow pain, medial condyle tenderness, and a subtle flexion contracture from the repetitive valgus stress of throwing. Overuse conditions in the lower extremities include Osgood–Schlatter disease and Sinding–Larsen–Johansson syndrome ("jumper knee"), which present as tenderness of the tibial tubercle and tenderness at the distal pole of the patella, respectively. Sever disease is an inflammation of the calcaneal physis where it joins the Achilles tendon. Severs tends to develop and flare during growth spurts; while painful, it is a temporary condition that will resolve with rest and symptomatic treatment. Medial tibial stress syndrome (MTSS or "shin splints"), which appear frequently with running sports, is a diffuse area of tenderness over the middle to distal third of the posterior-medial tibia. The diffuse tenderness of MTSS can be contrasted with the point tenderness of tibial stress fractures.

Ligamentous injuries are the topic of some debate because of the adage that "kids don't get sprains." However, the incidence of ligamentous injury (sprain) increases as patients approach adolescence. Sprains are becoming more apparent in young athletes, but they must still be carefully distinguished from the more common physeal fracture. Sprains are classified as mild (grade I), moderate (grade II), or severe (grade III). Ankle sprain is the most common joint injury in all of sports. The ankle is typically injured laterally owing to an inversion mechanism, and this mechanism may result in injury to the lateral ankle ligaments or the physis of the distal fibula.

Anterior cruciate ligament (ACL) knee injuries appear to be increasing, most likely because of improved recognition in addition to higher participation rates in sports. The usual mechanism of ACL injury is hyperextension, and this mechanism may result in either an ACL sprain or the previously mentioned tibial spine avulsion.

Sports injuries involving muscle are either contusions or strains. Contusions result from direct blows to the muscle, most of which are mild. However, complications can arise with hematomas in large muscle groups such as the quadriceps. A rare complication of contusions with intramuscular hematomas is myositis ossificans, a

benign proliferation of bone and cartilage that appears weeks after a large contusion. Muscle strains occur when a sudden contraction of a muscle results in stretching or tearing of muscle fibers. Strains usually occur at the point where muscle and tendon fibers join. The classic muscle strain is that of the hamstrings, where the individual cannot bear weight after experiencing a "pop."

Brachial plexus injuries ("stingers" or "burners") result from trauma to the neck and shoulder region. The nicknames for brachial plexus injuries come from the burning or stinging sensation that tends to radiate down one arm in a nondermatomal pattern. The differential diagnosis includes spinal cord injury, which must be excluded in any patient with bilateral upper extremity symptoms or radicular symptoms into the legs.

ED EVALUATION

Most sports injuries involve an injured extremity, and a standardized approach to evaluation is recommended. Adequate pain control prior to physical examination or radiographs cannot be overemphasized. The injured extremity should be fully exposed to reveal any erythema, ecchymoses, or swelling, and the region should be palpated closely for any point tenderness. Exposing the injured extremity for comparison is often helpful. Adjacent joints should be assessed for both active and passive range of motion. The Ottawa knee and ankle rules have been found to be highly sensitive in school-age children and should be applied when deciding whether radiographs are indicated. Adequate visualization requires at least two views, and often three.

Patients with brachial plexus injuries may have unilateral weakness of the deltoid, biceps, or rotator cuff. A positive Tinel sign at the supraclavicular fossa also suggests a plexus injury. Close inspection of the cervical spine is necessary to rule out a cervical spine injury.

KEY TESTING

- Radiographs are necessary to evaluate for fractures in children or adolescents

ED MANAGEMENT

The keys to ED management of sports injuries are pain control, injury recognition, proper immobilization, and appropriate consultation. Pain control is best provided prior to any detailed examination or imaging and permits a better physical examination, better radiographs, and less patient discomfort. The majority of sports injuries can be immobilized and seen by an orthopedist or sports medicine physician within 5 days. The exceptions to this rule are limb-threatening injuries, intra-articular fractures (Salter–Harris III and IV), markedly displaced fractures, and dislocated joints that cannot be successfully reduced. Proper immobilization does not differ from that employed with other musculoskeletal injuries. Ideally, the joints proximal and distal to an injury are immobilized. If this cannot practically be done, immobilization techniques should provide for stabilization and protection from further injury.

Dislocations require prompt recognition and pain control. After appropriate radiographs, procedural sedation is recommended for reduction. Numerous techniques exist for reducing dislocations, and ED physicians need to be familiar with the different approaches. After successful reduction, postreduction radiographs and immobilization are indicated.

Avulsion injuries of the lower extremities and pelvis are managed with crutches and non-weight bearing until follow-up. The management of ligamentous and tendinous injuries depends upon their severity. More severe injuries require immobilization until follow-up. Stress fractures also require immobilization, but most other overuse injuries merely require a cessation of the related activities. If there is any doubt, the best plan is to immobilize the affected area and arrange for close follow-up in 3 to 5 days.

Brachial plexus injuries without progressive symptoms require minimal ED management once the diagnosis is made, but any focal findings suggestive of intracranial bleeding or cervical spine injury

require emergent imaging. Chronic symptoms or persistent neurologic deficits are best evaluated with MRI.

CRITICAL INTERVENTIONS

- Emergent consultation for any injury with suspected neurovascular compromise or compartment syndrome
- Prompt reduction of any dislocated joint using analgesia and procedural sedation
- Emergent imaging for suspected cervical spine injury

DISPOSITION

Disposition and discharge instructions need to be emphasized in sports injuries. All of these patients need the classic "PRICE" discharge instructions covering the basics of *p*rotection, *r*est, *i*ce, *c*ompression, *c*ast/splint care, and *e*levation. Modifying this to "PRICE-FM" emphasizes *f*ollow-up, *m*edications, and *m*obility for ideal management. Follow-up should be scheduled for 3 to 5 days with an orthopedist, sports medicine physician, or primary physician. Opioids should be provided if necessary, although this should be rare. More commonly, nonsteroidal anti-inflammatory drugs suffice. Mobility and range of motion are emphasized for ligamentous and muscle injuries. Return-to-play decisions are best left to the physician who will be monitoring the patient's condition on follow-up.

Common Pitfalls

- Assuming that the young athlete with a sports injury has a sprain. The younger the athlete, the more likely an injury will result in a fracture.
- Forgetting to emphasize the importance of proper follow-up and rehabilitation.

ACKNOWLEDGMENT

The author gratefully acknowledges the contributions of Greg Canty to the content of this chapter.

PART 5 • SPECIFIC DISEASES

CHAPTER 254 Newborn Problems

Esther Yue

The evaluation of newborns can be challenging to emergency providers who are less familiar with complaints typically managed in the general pediatric ambulatory setting. It may be difficult to differentiate a well and thriving infant who requires no intervention and can be safely discharged home from the subtly ill infant who requires interventions and hospitalization. The goal of this chapter is to provide emergency medicine physicians with a review of benign, nonlife-threatening complaints that present in the newborn period.

During the first few months of life, an infant's job is to "eat, sleep, pee, poop, and breathe." As described in Chapter 215, a detailed history demonstrating the baby's normal performance of these basic functions can often exclude many serious pathologic conditions and reassure both parents and clinicians.

NEURO

Crying/Colic

All babies cry, but the intent behind the cry can be difficult for caregivers to interpret. Crying can be a sign of hunger, pain, distress, or fatigue. Crying for prolonged periods can be distressing for parents and prompt a visit to the clinic or emergency department (ED). It is helpful for clinicians to understand normal crying behavior. Between 2 and 6 weeks of life, the duration of crying *increases* from an average of 2 hours a day to an average of 3 hours a day. Crying then tapers down to an average of 1 hour a day by 12 weeks of life (1). "Excessive crying" or colic has been described as

crying for longer than 3 hours a day. (A more traditional definition is crying for longer than 3 hours a day, for more than 3 days per week, for more than 3 weeks). Colic has no identifiable etiology and may be the extreme of normal infant crying (2,3). Less than 5% of infants evaluated for excessive crying are found to have an organic etiology. Nonetheless, these infants should have a thorough physical examination to identify sources of pain, including skin lesions, corneal abrasions, hair tourniquets, or signs of abuse such as fractures or bruises. A more detailed investigation of the **crying infant** is described in Chapter 227. Although for most babies colic resolves by 12 weeks of life, 15% of infants with colic continue to have excessive crying beyond this time. Clinicians can help families to develop good techniques for soothing their infants such as swaddling, singing, white noise, gentle rocking, or gentle vibration. Equally important to emphasize are dangerous techniques to avoid, such as shaking a baby or placing a baby on a vibrating clothes dryer, which can result in falls. Babies with excessive crying are at risk of abuse; it is important for parents to find ways to manage their own stress, such as taking short breaks from caregiving (4).

Myoclonic Jerks

Newborns spend the majority of their time sleeping, up to 16 hours per day. In babies, sleep is categorized as active sleep and quiet sleep. Active sleep matures into random eye movement sleep (REM) in older children and adults, whereas quiet sleep becomes nonrandom eye movement sleep (NREM). It is typical for newborns to start their sleep cycle in active sleep, in contrast to children and adults who begin their sleep in NREM sleep. Each sleep cycle is approximately 60 minutes in length, as compared to 90 minutes in children and adults. There is significant motor activity during active sleep which some parents may mistake for seizure activity (1,5,6). Periodic breathing, rapid eye movements, and myoclonic leg jerking accompany active sleep (7). These normal movements, however, should be differentiated from signs of neonatal seizures such as rhythmic lip smacking, tongue thrusting, eye blinking, eye rolling, apnea, or bicycling or rowing movements. **Neonatal seizures** are

reviewed in Chapter 236. If there is any doubt, parents should be encouraged to keep a record of these movements and their timing so as to provide a more detailed history for the physician.

RESPIRATORY

Periodic Breathing

Newborns have a characteristic pattern of periodic breathing consisting of rapid breathing for 10 to 15 seconds followed by a pause for 5 to 10 seconds, with *no* cyanosis or significant hypoxemia. Periodic breathing has been attributed to an immature central nervous system. Pathologic apnea is typically defined as lasting longer than 20 seconds or being associated with cyanosis or significant hypoxemia. If parents describe episodes of cyanosis, or apnea longer than 20 seconds, those babies should have a more thorough evaluation for **Apparent Life-Threatening Event,** described in Chapter 233.

GASTROINTESTINAL

Newborns who are exclusively breastfed can lose up to 10% of their birth weight in the first few days of life, but should regain this weight by 7 to 14 days of life when maternal milk patterns are more regular. Formula-fed infants will lose some birth weight during the first few days of life but often regain the weight more quickly than breast-fed infants. Once birth weight is reestablished, babies gain approximately 30 g (1 oz) per day. Full-term infants require 100 kcal/kg/d to achieve adequate weight gain. A typical newborn drinks 15 to 30 mL (0.5 to 1 oz) of breast milk or formula per feed for the first few days, which is sufficient because of in utero nutritional storage. By the end of the first week, infants drink 2 oz approximately every 2 to 3 hours, and by the end of the first month of life, infants drink 3 to 4 oz approximately every 3 to 4 hours (3). Overfeeding of babies may result in postprandial emesis (see below).

Choice of Formula

Emergency providers may be unfamiliar with the various types of infant formula and with the indications for some babies to require specific types (Table 254.1). In most cases, infants should be on a cow's milk-based formula that is fortified with iron and provides 20 kcal/oz. Soy milk-based formula, also providing 20 kcal/oz, is indicated for infants who have temporary or chronic lactose intolerance or galactosemia. Changing to soy milk-based formula for a suspected milk protein allergy is *not* recommended because there is a 30% antigenic crossover between milk protein and soy protein. Instead, babies with milk protein allergy should be on hypoallergenic formulas such as extensively hydrolyzed protein or amino acid formulas (8,9). In general, changes to formula should not be made in the ED setting as these infants will require close follow-up, preferably by their general pediatrician or family doctor.

TABLE 254.1
Composition of Pediatric Formulas (per Liter) (10)

	kcal/oz	Protein Source	Protein gram	Fat Source	Fat gram	Carbohydrate Source	Carbohydrate gram	Suggested Use
Human Milk								
Term human milk	20	Human milk protein	11	Human milk fat	39	Lactose	72	Infants
Preterm human milk	20	Human milk protein	14	Human milk fat	39	Lactose	66	Preterm infants
Preterm Infant Formulas								
Enfamil Enfacare LIPIL (Mead Johnson)	22	Nonfat milk Whey protein concentrate	21	HO Vegetable oil Soy oil MCT oil Coconut oil DHA and ARA	39	Maltodextrin Lactose	77	Preterm infant after discharge from NICU
Similac NeoSure Advance (Abbott Ross)	22	Nonfat milk Whey protein concentrate	21	Soy oil Coconut oil MCT oil DHA and ARA	41	Corn syrup solids Lactose	75	Preterm infant after discharge from NICU
Cow's Milk-Based Infant Formulas								
Enfamil Premium (Mead Johnson)	20	Nonfat milk Whey protein concentrate	14	Palm olein oil Soy oil Coconut oil HO sunflower oil DHA and ARA	36	Lactose	74	Infants with normal GI tract
Enfamil A.R. (Mead Johnson)	20	Nonfat milk	17	Palm olein oil Soy oil Coconut oil HO sunflower oil DHA and ARA	34	Lactose Rich Starch Maltodextrin	74	Thickened feeding for infants who spit-up frequently
Good Start Supreme DHA and ARA (Nestle)	20	Enzymatically hydrolyzed reduced minerals Whey	14.7	Palm olein oil Soy oil Coconut oil HO safflower oil or HO sunflower oil DHA and ARA	34	Lactose Maltodextrin	75	Infants with normal GI tract
Similac Advance (Abbott Ross)	20	Nonfat milk Whey protein concentrate	14	HO safflower oil Soy oil Coconut oil DHA and ARA	37	Lactose	76	Infants with normal GI tract
Similac for Spit-Up (Abbott Ross)	20	Nonfat milk Whey protein concentrate	14	HO safflower oil Soy oil Coconut oil DHA and ARA	37	Lactose Rice Starch	76	Thickened feeding for infants who spit-up frequently
Soy-Based Infant Formulas								
Enfamil Prosobee LIPIL (Mead Johnson)	20	Soy protein isolate L-Methionine	17	Palm olein oil Soy oil Coconut oil HO sunflower oil DHA and ARA	36	Corn syrup solids	71	Infants with galactosemia or lactose malabsorption

	kcal/oz	Protein Source	Protein gram	Fat Source	Fat gram	Carbohydrate Source	Carbohydrate gram	Suggested Use
Soy-Based Infant Formulas								
Good Start Soy PLUS (Nestle)	20	Partially hydrolyzed soy protein isolate	17	Palm olein oil Soy oil Coconut oil HO safflower oil or HO sunflower oil DHA and ARA	34	Corn maltodextrin Sucrose	75	Infants with galactosemia or lactose malabsorption
Isomil Advance (Abbott Ross)	20	Soy protein isolate L-Methionine	17	HO safflower oil Soy oil Coconut oil DHA and ARA	37	Corn syrup Sucrose	70	Infants with galactosemia or lactose malabsorption
Casein, Extensively Hydrolyzed Infant Formulas								
Nutramigen (Mead Johnson)	20	Casein hydrolysate L-Cysteine L-Tyrosine L-Tryptophan	19	Palm olein oil Soy oil Coconut oil HO sunflower oil DHA and ARA	36	Corn syrup solids Modified corn starch	69	Infants with food allergies or protein malabsorption
Pregestimil (Mead Johnson)	20	Casein hydrolysate L-Cysteine L-Tyrosine L-Tryptophan	19	MCT oil Soy oil Corn oil HO sunflower oil	38	Corn syrup solids Dextrose Modified corn starch	69	Infants with food allergies, protein or fat malabsorption
Alimentum (Abbott Ross)	20	Casein hydrolysate L-Cysteine L-Tyrosine L-Tryptophan	19	Safflower oil MCT oil Soy oil DHA and ARA	37	Sucrose Modified tapioca starch	69	Infants with food allergies, protein or fat malabsorption
Amino Acid-Based Infant Formulas								
EleCare (Abbott Ross)	20	Free L-amino acids	20	HO Safflower oil MCT oil Soy oil	32	Corn syrup solids	72	Infants with severe food allergies, fat malabsorption
Neocate	20	Free L-amino acids	21	HO Safflower oil Coconut oil Soy oil	30	Corn syrup solids	78	Infants with severe food allergies

Physiologic Gastroesophageal Reflux

Many newborns regurgitate after meals. They have low tone in the lower esophageal sphincter, allowing stomach contents to move up into the esophagus with minimal pressure on the intra-abdominal region. As the lower esophageal sphincter becomes more competent, this benign condition typically resolves around age 3 to 6 months of age. The usual presentation of gastroesophageal reflux (GER) in infants is the production of frequent small mouthfuls of breast milk or formula in an *effortless* manner. There is no active emesis. See Chapter 223 for a comprehensive review of **vomiting** in children.

Common descriptions of GER by parents include “spitting up” or “wet burps.” These babies have adequate numbers of wet diapers,

and they have appropriate weight gain (about 30 g/d). This is to be differentiated from pathologic cases of gastroesophageal reflux disease (GERD), which are associated with more severe symptoms such as crying with regurgitation, back-arching, and recurrent coughing or wheezing. Babies with pathologic GERD may have poor weight gain, recurrent pneumonia from aspiration, or concomitant esophagitis (3,11,12).

Techniques to minimize benign GER include thickening feeds with rice or oatmeal cereal (1 tablespoon of cereal per 2 oz of formula), avoiding overfeeding, frequent burping while feeding, and holding the infant upright for 15 to 20 minutes after eating. A common mistake by caregivers is to place a baby in a semi-upright position (also known as semi-reclined) such as in a bouncy chair, car seat, or swing, immediately after feeding. The semi-reclined position increases intra-abdominal pressure, allowing stomach contents to regurgitate into the esophagus.

Constipation

While parents are often concerned about their babies spitting up, they are equally concerned about their stooling habits. Stool patterns vary. Breast-fed newborns generally stool more frequently than formula-fed babies. Babies who have not passed meconium in the first 48 hours of life require a more thorough evaluation for imperforate anus, intestinal obstruction (e.g., Hirschsprung disease), or hypotonia (see Chapter 230). In general, infants have 3 to 4 stools per day on days 3 to 4 of life, then 4 to 6 stools per day on days 4 to 6 of life, and 8 to 10 stools per day in weeks 2 to 4 of life. Normal stool patterns can range from once every 2 to 3 days to 8 to 10 times a day (9,13). After the passage of meconium in the first few days of life, the stool's appearance can vary in color and consistency, from loose watery yellow or green to more solid brown.

Constipation is defined as a difficulty passing stool or passage of hard, dry, pellet-like stools for 2 weeks (1). It is very rare for exclusively breast-fed babies to have constipation. The absence of bowel movements for up to 7 days can be normal in newborns and does not necessarily signify constipation. Clinicians can be reassured

if the baby continues to eat and void, and has a soft abdomen. Rectal stimulation in the ED with a rectal thermometer probe or lubricated cotton swab often results in a bowel movement by the end of the encounter.

Rice cereal can sometimes cause constipation, especially if more than the recommended 1 tablespoon per 2 oz of formula is added to thicken feeds for babies with GER (discussed above). In these cases, oatmeal cereal is an adequate substitution for rice cereal. Another treatment for constipation is to give infants fruit juice (prune, apple, or pear juice), starting with ½ oz of juice per day and not exceeding 2 oz of juice per day. Juice introduces an osmotic load into the intestinal lumen, causing more water to enter the gastrointestinal tract. If fruit juice does not produce regular soft stools, clinicians may advise glycerin suppositories as the next step. Mineral oil, molasses, and karo syrup are *not* recommended for the treatment of infant constipation.

Infantile Dyschezia

Infants may experience symptoms of straining for prolonged periods and crying, followed by a passage of *soft stool.* This pattern of difficult defecation is called infantile dyschezia, which is different from constipation, and is present typically in the first 6 months of life. In order to have successful passage of stool, babies need to coordinate intra-abdominal pressure increase and pelvic floor relaxation. Babies with infantile dyschezia have not developed effective coordination of these two events. Eventually, after a period of crying and straining, which increase intra-abdominal pressure, infants relax their anal sphincter and pass soft stools effortlessly. In time, babies learn to bear down (Valsalva maneuver) to increase their intra-abdominal pressure and have less difficulty with bowel movements (9,13). There is no treatment for this and in fact, routine treatments for constipation are not recommended for infantile dyschezia. Suppositories and rectal stimulation are not appropriate and can be counter-productive. Infantile dyschezia resolves spontaneously and rarely lasts more than 1 to 2 weeks.

GENITOURINARY

Voiding patterns vary among infants, but in general, they should produce 6 to 10 wet diapers per day. Most newborns should void at least once in the first 24 hours and pass meconium within the first 48 hours of life. Newborns generally void one time for each day of life: At least two voids per day on day of life 2, three voids on day of life 3, up to 10 voids by day of life 10.

Urate Crystals

Families may present to the ED with a diaper containing a pink crystalline substance or salmon-pink residue. This is the result of urate crystals being deposited in the diaper. Urate crystals are typically easily distinguishable from blood, but clinicians can perform occult blood testing if they are not sure. Urate crystals are usually found when there is concentrated urine, typically in the setting of dehydration. This should prompt the clinical to carefully assess hydration, including asking about the frequency of wet diapers, and checking for a sunken fontanelle or dry mucous membranes on physical examination. If there are concerns about the baby's hydration, parents should be advised to increase either the frequency or volume of feeds (3).

Vaginal Discharge

Because of transplacental passage of maternal hormones, normal newborn girls have well-estrogenized vaginal mucosa. The estrogenized mucosa produces a milky-white vaginal discharge which is a normal finding in newborn girls. Within the first week of life, newborn girls often have slight vaginal bleeding due to the withdrawal of maternal estrogen. Both of these are normal findings and parents can be reassured (3). If there is frank vaginal bleeding beyond a week of life, other diagnoses such as congenital endocrine disorders or sexual abuse need to be considered.

DERMATOLOGY AND OTHER CONSIDERATIONS

Oral Cavity

Primary teeth typically erupt at about 6 months of age, although this can range between 3 months and 16 months of age. **Natal teeth,** present at approximately the time of birth, are usually primary teeth that have erupted early. Natal teeth are typically poorly formed, with a thin layer of enamel, and are poorly attached to a mucosal stalk. In general, it is not recommended to remove these, since this may affect the spacing of secondary teeth. The only indications for removal of natal teeth are if they are causing significant irritation to the tongue or if they are an aspiration risk, given the poor attachment to the mucosal surface (14). Sometimes mistaken as natal teeth are **dental lumina cysts,** which are clear fluid-filled sacs located on the surfaces of gums. These cysts can be located bilaterally or quadrilaterally, are typically not painful, do not interfere with feeding, and disappear within a few weeks. Yellow-white collections of epithelial cells are called **Bohn nodules** when they are located on the alveolar ridge and **Epstein pearls** when they are found at the junction of the hard and soft palate. These cysts also require no treatment and disappear within a few weeks (15). These benign cysts should be differentiated from **oral thrush** caused by *Candida albicans,* which requires treatment. Thrush produces thick, white, adherent patches with surrounding erythema, located on the oral mucosa. Unlike residual breast milk or formula on the baby's tongue and buccal mucosa, thrush is quite adherent to the mucosal surface and difficult to scrape off with a tongue depressor. Babies typically have decreased feeding secondary to thrush, and they should be treated with a topical antifungal (usually nystatin solution). It should be emphasized to the family to avoid reinfection from pacifiers and nipples, so mothers will need topical antifungal therapy as well.

Benign Neonatal Rashes

Healthy newborns often present with benign rashes which can worry their caregivers. **Erythema toxicum neonatorum** is the most common newborn rash and develops *within 3 to 4 days after birth.* It is characterized by an eruption of 2-mm erythematous macules, papules, and pustules anywhere on the body. These lesions are not vesicular, not pruritic, and are typically not located on the palms and

soles. Erythema toxicum is transient, often erupting in crops and disappearing spontaneously. There is no treatment, but it often resolves by 2 weeks of age.

Another benign neonatal rash is **transient neonatal pustular melanosis,** more commonly seen in darker pigmented babies. This is characterized by pustules and vesicles without underlying erythema that are present *at birth.* The pustules then rupture and leave behind collarettes of scale and hyperpigmented macules that fade and resolve spontaneously after a few weeks.

Maternal hormonal stimulation may be the cause for **infantile seborrhea dermatitis,** but the cause is largely unknown. Babies present during the first few months of life with greasy yellow scales and sometimes underlying erythema, fissuring, and oozing. When localized to the scalp, these patches are sometimes called "cradle cap," but they can appear on the ears, face, trunk, and flexural areas as well. The lesions are not pruritic, which distinguishes it from atopic dermatitis. Parents can gently loosen the scales with a soft brush while shampooing the area. Application of an emollient or oil before shampooing the area may help to soften the scales. More severe cases can be treated with an antifungal shampoo or mild topical corticosteroid (16,17).

Mastitis

Most term infants, both boys and girls, will have breast buds. Sometimes there is hypertrophy of these breast buds as a result of maternal hormones passing through the placenta in utero. In up to 6% of normal infants, maternal estrogen or neonatal prolactin actually causes **galactorrhea,** which is a thin milky discharge from the hypertrophied breast buds. Both galactorrhea and breast hypertrophy resolve within several weeks, although sometimes breast hypertrophy may persist slightly longer in baby girls. Families should be counseled on the potential for **mastitis,** an infection in hypertrophied breast buds, typically caused by *Staphylococcus aureus.* While most commonly caused by gram-positive bacteria, this infection can also be the result of gram-negative organisms. The breast bud is red, warm, swollen, tender, and sometimes has purulent

drainage or fluctuance suggestive of a breast abscess. Babies with mastitis typically have no systemic signs and symptoms such as fever, vomiting, lethargy, or irritability. If there are *no* associated systemic symptoms, mastitis can be treated first with intravenous, and then oral, antibiotics with good *S. aureus* coverage. Appropriate cultures, including culture of nipple drainage if present, should be obtained before starting treatment (18,19).

Diaper Rash

Diaper rash occurs frequently during the newborn period. Moisture from wet diapers promotes both skin irritation and the growth of *C. albicans*. Contact dermatitis appears as simple redness in the diaper area, with distinct borders at the diaper edges and sparing of the skin folds. Infants have sensitive skin and some babies have a reaction to the coloring dye used in some diapers. For contact dermatitis, using dye-free diapers, changing diapers more frequently, and applying a protective agent such as zinc oxide ointment are usually sufficient. For severe cases, a brief course of a mild topical corticosteroid may be indicated.

Candida diaper rash has a well-defined erythematous appearance, with satellite lesions and small pustules, and generally involves the skin folds. Application of nystatin or clotrimazole ointment to affected areas with each diaper change cures most cases (20). As yeast thrives in the moist environment of wet diapers, caregivers should be advised to apply the antifungal ointment for a few days beyond resolution of the rash. If diaper dermatitis is recalcitrant, other diagnoses such as zinc deficiency should be considered (21).

Common Pitfalls

- Babies with excessive crying are at risk of abuse; outline ways for caregivers to manage their own stress.
- A history of effortless gastroesophageal reflux in a thriving infant does not warrant blood work or imaging.
- Avoid making any infant formula changes in the ED; this should be left to the primary care provider to ensure close monitoring.

- Normal infant stooling patterns can vary widely and usually do not require any interventions.

CHAPTER 255

Eye Disorders

Janet G. Alteveer and Dunisha G. Ranasuriya

Ophthalmologic disorders in children represent a wide variety of diseases, both congenital and acquired, the diagnosis of which hinges on a careful history and a thorough examination of the eye. The elements of the examination change with patient age and developmental stage. Most children with ophthalmologic emergencies present to the ED with eye redness, eye swelling, or abnormal vision.

THE PEDIATRIC EYE EXAMINATION

A complete pediatric eye examination includes inspection of the eyelids, conjunctivae, pupil, and iris; evaluation of the extraocular muscles; fundoscopy; and testing of visual acuity. This examination is an essential part of the evaluation in any child presenting primarily with ophthalmologic conditions such as conjunctivitis, periorbital edema, visual change or loss, and trauma or neurologic complaints.

Inspection of the eyelids and conjunctivae should document the presence of erythema, ecchymosis, edema, proptosis, or masses. The cornea should be evaluated for normal contour and clarity. A bulging or hazy cornea in a neonate may indicate congenital glaucoma. The cornea should be stained using topical anesthetic drops and fluorescein test strips after rest of the examination is completed so as not to interfere with visual acuity testing. Shining a Wood light on the cornea in a darkened room will reveal stain adherent to corneal defects caused by an abrasion, herpetic infection, or ulcer. The pupil should be assessed for contour, bilateral symmetry, and reactivity to light. An abnormally shaped or reactive pupil may indicate defects in

the iris or disruption of the afferent or efferent nerve pathways to the eye.

Extraocular muscle testing can be accomplished by 4 months of age. By this age, a normal, full-term infant should be able to fixate on and follow a small, brightly colored toy held 6 to 12 in from the baby's face. By 5 to 6 months, the infant should fixate and follow an object through the full range of motion. By 2 to 3 years of age, most children, with gentle encouragement, will follow a light or finger.

Evaluation of the posterior chamber via direct ophthalmoscopy is dependent on the child's age and cognitive development, becoming easier as cooperation increases. The use of a short-acting topical parasympatholytic such as tropicamide (Mydriacyl 0.5%) will facilitate the examination of the retina. To encourage the child to look beyond the examiner and away from the direct light, use a brightly colored toy or have the parent wave at the child from directly behind the examiner. The minimum examination in an infant is the documentation of a normal red reflex. The presence of an abnormal red reflex (leukocoria or white reflex), which could indicate a cataract or intraocular tumor, mandates formal consultation with a pediatric ophthalmologist.

The corneal light reflex, or Hirschberg test, is useful in detecting strabismus or an ocular muscle palsy. It is conducted by shining a penlight, held 3 ft (1 m) away, centrally onto the child's face. In a normal child, the light will reflect centrally on both pupils when the child is fixated on the light or a small toy held in front of the face. If the light reflex is eccentric on one eye, a strabismus or palsy is present.

Visual acuity testing is an extremely important aspect of the complete eye examination. The manner of testing is dependent on the age and cognitive ability of the child. Visual acuity also varies by age (Table 255.1). To assess an infant, have the baby fixate (on a bright toy or light) and cover one eye gently with your thumb. If the uncovered eye has normal vision, the child will continue to fixate on the object. If the uncovered eye has poor vision, the child may lose interest, push the covering thumb away or protest.

TABLE 255.1
Visual Acuity by Age

Age	Visual Acuity
6 mos	20/60–20/100
3 yrs	20/25–20/30
5–7 yrs	20/20–20/25
By 8 yrs	20/20

By 3 years of age, depending on developmental and cognitive ability, more objective visual testing can be achieved. The Allen chart, HOTV matching test, or "Tumbling E" game can be used. By 5 years of age, most cognitively normal children can use the Snellen chart. Testing with the Snellen, Tumbling E, or HOTV chart should be performed at a distance of 20 ft (6 m). The Allen test can be performed at 10 ft (3 m).

In all of these charts, letters or objects are presented as a group. Children with poor vision have increased difficulty identifying objects when presented as a group (the crowding phenomenon) and will perform better when objects are presented singly.

CONJUNCTIVITIS AND THE RED EYE

CLINICAL PRESENTATION

Conjunctivitis results in 5 million outpatient visits per year (1) or 1% to 4% of all pediatric ambulatory complaints (2). The causative agent may be either bacterial, viral, allergic or chemical. Bacterial conjunctivitis predominates in infants and young children: 55% to 78% in recent studies (3). Common pathogens in young children are nontypable *Haemophilus influenzae, Streptococcus pneumoniae,* and *Moraxella catarrhalis. Staphylococcus Aureus* may be the causative agent in any age group and the incidence of methicillin-resistant *S. aureus* (MRSA) approaches 30% in some urban areas (4).

Neisseria meningitides and *Neisseria gonorrhoeae* are uncommon pathogens. Gonococcal conjunctivitis may occur occasionally outside of the neonatal period and in the prepubescent child who is not sexually active. Sexual abuse must be ruled out in these cases;

however, transmission from infected caregivers not abusing the child has been reported (5).

Infectious neonatal conjunctivitis is most commonly caused by *Chlamydia trachomatis,* followed by *N. gonorrhoeae* (ophthalmia neonatorum), and herpes simplex virus (HSV). The infant is infected at birth during passage through the vaginal canal. Women are routinely screened during pregnancy and prior to delivery so that risk factors would be absence of prenatal care, substance use, or history of a sexually transmitted infection. Neonatal prophylaxis for ophthalmia neonatorum is recommended universally in the United States. Currently only 0.5% erythromycin ophthalmic ointment is available in the United States, however, only silver nitrate solution is effective in prevention of infection by a penicillinase-producing gonococcus. The incubation period for gonococcal conjunctivitis is 2 to 7 days. Neonatal chlamydial conjunctivitis develops a few days to several weeks after birth. Fifty percent of infants born to infected women acquire *C. trachomatis,* and, of those, 25% to 50% develop conjunctivitis. Neonatal ophthalmic prophylaxis is not effective in the prevention of chlamydial conjunctivitis. Neonatal HSV infection occurs in 1 per 3,000 to 1 per 20,000 live births. The infant is mostly at risk if the mother has a primary infection at the time of delivery. The risk to an infant born to a mother with a recurrent infection is much lower. Neonatal HSV infections are of three types: generalized infection (25%), localized central nervous system (CNS) infection (30%), or disease of the skin, eye, and mouth (45%) (5). In addition, the above neonates may develop conjunctivitis due to gram-negative bacteria such as *Klebsiella* or *Pseudomonas* while in the NICU.

Bacterial conjunctivitis is most often bilateral and occurs predominantly in infants and preschool-aged children. It tends to come on abruptly and not be associated with fever or sore throat. In a recent study the history of “gluey” or “sticky” eyelids in the morning and physical findings of mucoid or purulent discharge demonstrated the highest likelihood for bacterial disease, whereas watery discharge and burning were more likely indicative of viral etiologies. Other low-risk predictors for bacterial disease include age greater than 6 years, onset between April and November, watery

discharge, and the absence of adherent eyelids upon awakening. The presence of three factors predicted a negative conjunctival culture 76% of the time, while the presence of all four factors was predictive of a negative culture 92% of the time (1). *N. gonorrhoeae* typically causes copious purulent exudates in all age groups referred to as a waterfall discharge. A neonate with ophthalmia neonatorum may appear toxic, with a copious purulent discharge. *C. trachomatis* infection causes a beefy red conjunctiva (5).

Viral conjunctivitis is often bilateral, occurs in school-aged children, often has a copious and clear discharge (however, a mucopurulent discharge may be present) and the presence of a conjunctival inflammatory membrane is diagnostic. Marked periorbital edema can be present, and should not be mistaken for periorbital cellulitis (POC). Significant eye pain suggests the likelihood of an etiology other than simple conjunctivitis, such as corneal abrasion, herpetic infection, or anterior uveitis.

In the summer, adenoviruses may predominate, particularly among children older than 6 years. Adenoviral conjunctivitis may be associated with two distinct clinical syndromes: pharyngoconjunctival fever and epidemic keratoconjunctivitis. Pharyngoconjunctival fever is caused by adenovirus types 3 and 7. It is most commonly spread by person-to-person contact but has also been reported to be spread through swimming; thus, the infection may be referred to as “swimming pool” conjunctivitis. Adenovirus types 8, 19, and 37 cause epidemic keratoconjunctivitis. This entity is transmitted by direct contact with infected people or contaminated instruments and is often iatrogenic. Attention to frequent hand washing prevents transmission (6).

Contact lens use is increasing in children and adolescents who may not always adhere to proper hygiene and lens disinfection procedures, put themselves at increased risk of pseudomonas and acanthamoeba infection (7).

Nontypable *H. influenzae* commonly causes concomitant otitis and conjunctivitis, which may play a role in the etiologies of infection in children less than 6 years old, where 25% with bacterial conjunctivitis also have otitis media.

HSV infection of the eye may be bilateral and is frequently accompanied by involvement of the skin and mouth. Skin and mouth lesions may not be present at the time of presentation, however; furthermore, the characteristic dendrites (seen on fluorescein staining) may be observed in only 30% of patients (8). This may lead to significant delay in diagnosis in cases where HSV presents only as a nonspecific appearing recurrent blepharoconjunctivitis with no fluorescein findings. Failure to diagnose HSV stromal disease in a timely manner can lead to significant scarring and potential vision loss (8). Herpes zoster virus (HZV) infection of the first division of the trigeminal nerve may affect the eye. There may be characteristic vesicular lesions on the forehead and eyelid. The conjunctivae are usually injected and fluorescein staining may show pseudodendrites. HZV is a unilateral infection and often, periorbital pain precedes the appearance of the vesicles (5).

Rarely, the red eye may be due to keratitis from HSV or HZV infection. Herpesviruses can cause ocular involvement during primary or recurrent infections. HSV is ubiquitous and is transmitted from person to person during primary and recurrent infections that may or may not be symptomatic. Periocular inoculation can occur from the HSV-1 perioral infections. Herpes zoster represents a reactivation of latent varicella-zoster virus. When it occurs in the dermatomal distribution of the trigeminal nerve, it can cause keratitis with conjunctivitis (5).

The most common cause of allergic conjunctivitis in children is seasonal rhinoconjunctivitis. The symptoms are caused by a localized IgE-mediated hypersensitivity reaction to airborne allergens, with resultant release of histamine and other products from mast cells. Pollens and grasses are the most common allergens. In up to 25% of children, ocular findings may be the sole manifestation (6). The findings are caused by the release of products from mast cells, predominantly histamine. Allergic conjunctivitis is bilateral with variable conjunctival injection and watery eye discharge. Other allergic symptoms such as boggy nasal turbinates, watery nasal discharge, and allergic shiners (dark circles around the eye), may or may not be present.

Chemical conjunctivitis is most often caused by ocular medications. Neomycin has the greatest incidence of contact sensitivity. Silver nitrate was a common cause in the neonate. Accidental environmental exposure to a toxin, such as cleaning agents, is also common. Chemical conjunctivitis presents with conjunctival injection and often, a burning sensation.

A host of other entities may present as a red eye. Corneal abrasion may present with a unilateral red eye. In the preverbal child it may be difficult to obtain the history of trauma to the eye. There is generally tearing, pain, and photophobia. Anterior uveitis classically presents with eye pain, a constricted pupil, potentially decreased visual acuity, and perilimbic injection of the conjunctiva (injection that is limited to the area of the conjunctiva surrounding the cornea) (9). Five percent of uveitis in the United States presents in children younger than 16 years and 41% of cases are associated with juvenile rheumatoid arthritis. Toxoplasmosis accounts for approximately 10% of cases. HSV and HVZ may also cause uveitis. Uveitis in children is a chronic disease with a high incidence (up to 20%) of developing blindness in one eye (9).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of the red eye is extensive and includes bacterial, viral, allergic, and chemical causes. More specific considerations should include Kawasaki disease, blepharitis, dacryocystitis, corneal abrasions, dry eye syndromes, and Parinaud oculoglandular syndrome (catscratch disease) involving the conjunctiva and an ipsilateral preauricular lymph node.

ED EVALUATION

The ED evaluation of the red eye begins with a detailed history and physical, including a complete age-appropriate eye examination. A slit-lamp examination in an older child who is cooperative is helpful. Outside of the neonatal period, conjunctival cultures are usually obtained only in recurrent cases or those unresponsive to initial treatment. An office-based, rapid adenovirus detector test is available with a sensitivity of 89% and a specificity of 94%; it may be useful in

the clinically unclear case (10). Fluorescein staining should be considered, especially with severe photophobia or corneal changes. Keratitis may appear as punctuate spots on the corneal surface. A Gram stain should be obtained if the discharge is copious, suggesting *N. gonorrhoeae* infection.

All young infants in whom the diagnosis of ophthalmia neonatorum or skin, eye, and mouth disease secondary to HSV is being considered must undergo a full evaluation for disseminated disease. This evaluation must include blood and cerebrospinal fluid (CSF) studies (complete blood count, chemistries, blood culture, CSF culture for bacteria and viruses, glucose, protein, Gram stain), conjunctival cultures for bacteria and viruses should also be obtained. In suspected gonococcal infection, a Gram stain of the eye drainage may be diagnostic and aid in early confirmation. A Tzanck preparation may be useful in herpetic infections. A conjunctival scraping for epithelial cells is more sensitive than swab cultures. When a chlamydial infection is suspected, cultures or specimens for rapid antigen testing of the conjunctiva and nasopharynx should be obtained using a Dacron swab (5). A chemical conjunctivitis is suggested when a history of ocular exposure to a toxin or ophthalmic medication is obtained in the presence of conjunctival injection.

Anterior uveitis is diagnosed with the slit lamp, showing cells (leucocytes) and flare (protein) in the anterior chamber. A corneal abrasion will also be evident on fluorescein staining with or without slit-lamp evaluation.

Fluorescein staining should identify the abrasion. Eversion and examination of the palpebral conjunctiva is necessary to ensure that there is no retained foreign body.

KEY TESTING

- Fluorescein examination
- Gram stain in suspected gonoccocal conjunctivitis
- Slit-lamp evaluation in the cooperative child

ED MANAGEMENT

The management of conjunctivitis is dependent on the suspected etiology and the age of the child. Treatment ranges from supportive care to hospital admission for parenteral antibiotics. Bacterial conjunctivitis, although a self-limited disease, is most frequently treated with topical ophthalmic antibiotics because this results in a bacterial cure and faster clinical improvement (11). This in turn allows children to return to day care or school and their parents to return to work. The ideal topical antibiotic should be broad spectrum, rapidly bactericidal, nontoxic to the eye, easy to use, inexpensive, and have low-resistance rates to the most common pathogens. Unfortunately bacterial resistance continues to rise: 29% of *H. influenzae* and 60% of *S. pneumoniae* exhibit resistance to penicillins and only 44% of the *S. pneumoniae* sp are included in the pneumococcal vaccine; *S. aureus* resistance to the older quinolones is increasing and while the newer quinolones (moxifloxacin and besifloxacin) have improved profiles against gram-positive organisms; they are expensive. Polymyxin B/trimethoprim has decreased efficacy against *H Influenzae* and *S pneumoniae* however trimethoprim is still effective against MRSA (4). Sulfonamides are no longer recommended because of increasing bacterial resistance and significant discomfort on instillation. Gentamicin and tobramycin are toxic to the corneal epithelium and should be reserved for gram-negative organisms (4). Choice of topical antibiotic should reflect the antibiogram of the community and also be somewhat case specific: is this a young child with presumed *H. influenzae* sp. or other common organism? Is there a risk of MRSA? Or is this a contact lens wearer with a high risk of *pseudomonas sp?*

In the instance of conjunctivitis–otitis syndrome, oral therapy with an appropriate antibiotic to treat *H. influenzae,* such as amoxicillin–clavulanate, will cure both the otitis and the conjunctivitis. Oral therapy for conjunctivitis without otitis has been shown to decrease the occurrence of otitis in the ensuing 2 weeks. Further data are needed to substantiate the efficacy of oral treatment of conjunctivitis. Meningococcal and gonococcal conjunctivitis is treated with systemic antibiotics.

Table 255.2 lists the etiologies of neonatal conjunctivitis with the indicated treatment.

TABLE 255.2
Etiology of Neonatal Conjunctivitis and Therapy

Organism	Medications	Other Therapy
N. gonorrhoeae	Ceftriaxone 25–50 mg/kg IV or IM, given once[a] Or Cefotaxime 100 mg/kg IV or IM	Frequent eye irrigation with saline
C. trachomatis	Erythromycin 50 mg/kg/d divided qid PO for 14 d	
Herpes simplex virus	Acyclovir 60 mg/kg/d IV divided q8h Duration: 14–21 d and 1–2% trifluridine, 1% iododeoxyuridine, or 3% vidarabine, applied topically	Ophthalmologic consultation

Data from American Academy of Pediatrics (Red Book).
[a]For prophylaxis of neonates, ceftriaxone 25–50 mg/kg single dose not to exceed 125 mg.

Localized HSV infections involving the eye should be treated with acyclovir 60 mg/kg/d in three divided doses for children younger than 1 year of age, and for older children, 1,500 mg/m^2/d in three divided doses for 7 to 10 days. Higher dosing and intravenous (IV) dosing (maximum 80 mg/kg/d) are used for disseminated or CNS disease (5,8). Some sources also advocate initiating topical antivirals (5). Acyclovir-resistant herpesvirus (an issue usually only with HIV-infected children previously exposed to acyclovir) is treated with foscarnet 80 to 120 mg/kg/d in two or three divided doses, although there is insufficient data for the appropriate dosage in children (5).

Adenoviral conjunctivitis is treated with supportive therapy. To prevent the spread of infection to other family members, the family should be counseled to wash hands frequently and to avoid sharing washcloths. The infected child should be kept away from immunocompromised persons and neonates, because this group is at increased risk for severe disease. The child should also be kept home from school or day care for 5 to 7 days.

The treatment of allergic conjunctivitis is avoidance of the allergen and topical therapy with vasoconstrictors and cool compresses. There are a number of topical H_1 blockers on the market as well as mast cell stabilizers such as lodoxamide or nedocromil. These latter may be more effective than topical nonsteroidal anti-inflammatory drugs (NSAIDs); however, they may require several days to a few weeks to effect symptom improvement (6).

Corticosteroid-containing eye drops have no place in the treatment of acute conjunctivitis. They may be necessary in the treatment of uveitis or severe keratitis but should be used only after consultation with an ophthalmologist. Long-term use of steroid drops can endanger vision by causing cataracts or glaucoma. Short-term use may inhibit the hosts' ability to limit infection and prolong viral shedding in contagious conjunctivitis. Corticosteroid/antibiotic combinations may also promote or increase the severity of fungal keratitis.

The cornerstone of treatment of chemical exposure is decontamination: copious flushing of eye exposure with water or normal saline. This is followed by visual acuity testing, fluorescein staining, and slit-lamp evaluation.

Corneal abrasions are treated symptomatically and often with antibiotic drops as well. Contact lens wearers should be prescribed a fluoroquinolone preparation because of the concern for pseudomonas. Eye patching has not been shown to be of benefit and may retard healing in abrasions <10 mm in length (12). Cycloplegics, thought to relieve pain from ciliary muscle spasm, also may not be effective. Ketorolac drops, although safe, are expensive (6).

DISPOSITION

Bacterial conjunctivitis, with the exception of gonococcal disease, outside of the neonatal period is an outpatient disease. Follow-up with a primary care provider should be recommended. School districts have policies with regard to when children with presumed bacterial conjunctivitis may return to school. Many will allow children who have been on 24 hours of antibiotic drops to return to

class. Viral conjunctivitis is much more infectious; if there is keratitis they should be referred to an ophthalmologist for follow-up.

If large corneal defects, especially those involving the visual axis are detected, emergent ophthalmologic evaluation is necessary. All cases of suspected ophthalmia neonatorum, HSV, and HZV ophthalmic infection as well as anterior uveitis should be referred to a pediatric ophthalmologist emergently. The risk for ocular damage and permanent visual loss is significant.

Neonatal, herpetic, meningococcal, and gonococcal conjunctivitis requires inpatient therapy at a facility well versed in pediatric care with pediatric ophthalmologic resources. When chlamydial infection is suspected, consultation with a pediatrician is helpful.

Significant chemical exposures should be referred to an ophthalmologist.

Common Pitfalls

- Failure to recognize herpetic infection of the eye. Delay in treatment can often lead to visual loss, CNS disease, or systemic disease.
- Inappropriate use of corticosteroid-containing eye drops, unless discussed with an ophthalmologist.
- Ignoring the presence of eye pain which may indicate corneal abrasion, herpetic infection or anterior uveitis

PERIORBITAL&NDASH;ORBITAL CELLULITIS AND THE SWOLLEN EYE

CLINICAL PRESENTATION

Children with a swollen, red eye are a relatively common problem in the ED. POC, also called preseptal, and orbital cellulitis (OC) are distinct clinical entities with different pathogenesis and treatment (13). *POC* is defined as an inflammatory or infectious process superficial to the orbital septum while *OC* is an inflammation or infection *deep* to the orbital septum. OC may involve the ocular structures, causing abscess formation, most commonly subperiosteal,

and vision loss. The veins draining the periorbital skin and soft tissues, orbital structures and ethmoid and maxillary sinuses are valveless and anastomosing, allowing easy spread of infection to the cavernous sinus and CNS (14).

POC may occur via two different routes. The skin barrier near the eye may be broken by local trauma, an insect sting, or an HZV lesion with local spread of infected material to the periorbital tissues. Alternatively, there may be seeding of periorbital tissues from bacteremia, often several days after onset of an upper respiratory infection (URI). OC develops from sinusitis, most often beginning with formation of a subperiosteal abscess that then spreads into the orbital tissues. The ethmoid sinus develops earliest, so younger children present with ethmoiditis and ethmoid sinusitis. In older children, the frontal sinuses can be the origin of infection. Uncommonly, OC results from extension of infection through natural bony dehiscences of the ethmoid bones, which form the medial wall of the orbit. In one recent study, OC occurred with a similar frequency in older and younger children and ethmoid sinusitis was present in 98% of the study population. Figure 255.1 shows the close proximity of the sinuses to the orbital cavity (13).

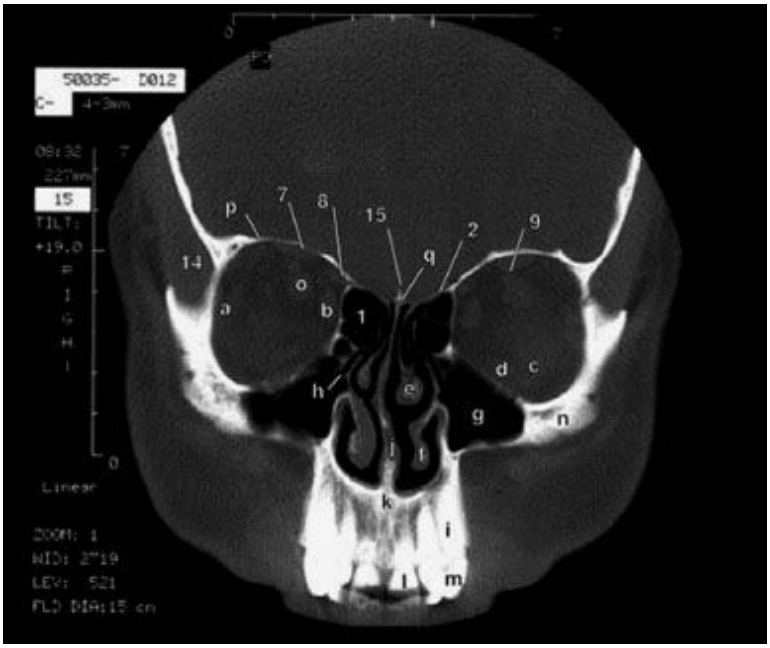

FIGURE 255.1 General anatomy imaging and technology CT and MRI.

The thin skin and loose connective tissue of the eyelid allow for easy and rapid accumulation of fluid. A child with POC/OC may often present within hours of onset with a red and swollen eyelid. Ninety-five percent of cases are unilateral, with the actual color of the lid described as violaceous or purple. Seventy-five percent of children are febrile. Two-thirds will have an upper respiratory infection; one-third, a history of minor trauma; one-fourth, an acute otitis media; and one-fifth, an associated conjunctivitis (15). In bacteremic or posttraumatic POC, palpation of the periorbital tissues will elicit tenderness, but the eye itself should move freely and painlessly. In inflammatory POC due to an underlying sinusitis, the periorbital tenderness is variable. The edema may initially present in the early morning and be intermittent with resolution of edema as the day progresses. In advanced OC, the eye may be proptotic and extremely painful to voluntary movement of the extraocular muscles and visual acuity may be reduced. There may be diplopia on upward gaze. The child may appear "toxic" or irritable, with early meningeal signs.

A bacterial pathogen in POC/OC is identified, mostly, by blood culture in only 30% of cases. Prior to the introduction of the *Haemophilus influenzae type b* (HiB) and *S. pnemoniae* vaccines, 80% of the cultures in bacteremic POC, were positive for *H. influenzae;* with the remaining cases due to *S. pneumoniae.* Widespread usage of vaccines has resulted in a significant decrease in the incidence of bacteremic POC (16). The agents causing OC or inflammatory POC are the same that cause acute sinusitis: *S. pneumoniae,* nontypable *H. influenzae,* and *M. catarrhalis* (14). Since 2000, however there has been a significant decrease in invasive pneumococcal disease, as well as a decrease in drug-resistant *S. pneumoniae.* Consequently there has been a concomitant increase in both disease and colonization by nonvaccine serotypes; fortunately these organisms are less likely to cause invasive disease.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of the swollen eye beyond orbital and periorbital cellulitis includes local allergic reaction, trauma, sinusitis, bulbar or retrobulbar neoplasms, and dacryoadenitis (inflammation or infection of the lacrimal gland).

ED EVALUATION

The examination of the eye must include not only gentle palpation of the periorbital area but also an assessment of whether the globe is proptotic, the function of the extraocular muscles, and whether there is any pain with movement of the eye. Visual acuity, pupillary function, and confrontation visual fields must be assessed, if necessary, with the use of lid retractors. Specialists currently use a staging process of stage I to IV with stage I being POC and stage II through IV reflecting increasingly severe levels of OC (15).

Laboratory studies are of limited value, although a white blood cell count >15,000 may suggest bacteremia. Cultures of any wounds near the eye should be obtained; keeping in mind, conjunctival or nasopharyngeal swabs are generally not helpful. Blood cultures have been reported to be positive in up to 30% of children; however 70% to 80% of these were *H. influenzae* in the prevaccine era (13). It seems like blood cultures will identify fewer and fewer organisms. In the pre-HiB era, lumbar puncture (LP) was considered almost mandatory in the young child because of the invasive and virulent character of *H. influenzae* bacteremia. Currently, most authors reserve LP for children younger than 1 year of age with increased risk of *S. pneumoniae* bacteremia (13), those who are “toxic” or irritable, or those who have not yet received or completed the Hib and pneumococcal vaccination series.

Computed tomography (CT) of the orbit is useful in delineating sinusitis, subperiosteal and orbital abscesses, orbital involvement, or intracranial extension. It should be reserved for the child who presents with proptosis, pain on extraocular movement, limitation of eye movements, double vision, vision loss, ANC >10, 000 cell/μL or inability to conduct a full eye examination (12,13).

KEY TESTING

- Culture of any open wound(s) near the eye
- Blood cultures
- CT with IV contrast

ED MANAGEMENT

For OC: After appropriate cultures have been obtained, an IV line should be started and antimicrobial therapy initiated with an eye to covering the most likely organisms (Table 255.3). Subspecialty consultation with an ophthalmologist is mandatory.

TABLE 255.3
Antibiotic Treatment of Orbital Cellulitis

S. pneumoniae *M. catarrhalis* Nontypable *H. influenzae* Ceftriaxone 50–75 mg/kg IM or IV q24h or Cefotaxime 50 mg/kg per dose q6h plus Clindamycin 10 mg/kg per dose q8h or Nafcillin 100–200 mg/kg/d divided q6h or Augmentin/sulbactam 200 mg/kg/d divided q6h plus Vancomycin 60 mg/kg/d divided q6h[b]	High prevalence of community-acquired MRSA For moderate infections: Clindamycin 40 mg/kg/d divided q6–8 (max 2.7 g/d)[a] For severe infections: Vancomycin 60 mg/kg/d divided q6–8 (5) Fluoroquinolones not approved for use in young children

[a]There have been documented treatment failures due to inducible resistance in erythromycin-resistant strains (5).
[b]If suspicious for highly resistant *S. pneumoniae*.

For POC: The choice of outpatient antibiotics should reflect the level of antibiotic resistance within the community to *S. pneumoniae,* group A *Streptococcus,* and *S. aureus.* Blood cultures should be drawn prior to antibiotics. Treatment recommendations are presented in Table 255.4.

TABLE 255.4
Outpatient Treatment of POC

Condition	Gram + Organisms	High Prevalence of MRSA
Uncomplicated posttraumatic (no purulent draining wound)	Cephalexin, doxycycline (children >8 yrs) or clindamycin (1)	Clindamycin 30 mg/kg/d divided every 6–8 hrs or trimethroprim–sulfamethoxazole 6–10 mg/kg/d of TMP divided every 12 hrs
Nontraumatic	Ceftriaxone 50 mg/kg (not to exceed 1 g) followed by ampicillin–clavulanate 45 mg/kg/d in two divided doses for 7–10 d Penicillin allergic: Azithromycin 12 mg/kg (max 500 mg/d) once a day for 5 d	Same as above

DISPOSITION

All children with OC should be admitted to the hospital. Immediate consultation with an ophthalmologist and/or otolaryngologist should be undertaken if there are any physical findings suggestive of orbital involvement (proptosis, pain on eye movement, or decreased visual acuity), if there is difficulty obtaining an adequate eye examination, or if there has been failure to respond to parenteral antimicrobial therapy. Surgical evacuation is currently recommended for those patients who develop optic nerve findings such as decreasing visual acuity, afferent pupillary defects, visual field deficits, or who do not respond to 24 to 36 hours of medical management (13). The presence of sinusitis should prompt an otolaryngologic evaluation for possible endoscopic sinus surgery.

Recently, selected children with POC have been managed on an outpatient basis. There are several criteria that must be met before the child can be discharged: (1) There must be *no* orbital involvement (proptosis, ophthalmoplegia, or decreased visual acuity), (2) the child should be well-appearing, and (3) caregivers must demonstrate willingness to take the child home and to return the child immediately to the ED should the child's condition deteriorate. The child will need to have daily examinations to document resolution until blood cultures are negative (usually 48 hours) (15,17).

Common Pitfalls

- Failure to conduct a thorough eye examination, thus missing signs of orbital involvement.
- Failure to consult an ophthalmologist and or an otolaryngologist early in cases of orbital involvement, which could result in a poor outcome, possible visual impairment, or loss of the eye.

VISUAL DISTURBANCE

CLINICAL PRESENTATION

The clinical presentation of visual loss varies with age and developmental stage. An infant may be brought to the ED because parents have noted unilateral swelling of the globe or haziness of the cornea. Parents may complain that the 2- to 3-month-old infant does not seem able to fixate on and follow objects. There may be no complaints at all, and the physician may discover one of these findings incidentally or note an abnormal red reflex or the presence of nystagmus.

The parents of a preverbal child may bring them to the ED because of perceived strabismus or a persistent head tilt. Intraocular tumors may present with decreasing visual acuity, leukocoria (absent red reflex), strabismus, or gradually increasing proptosis and corneal edema. Rhabdomyosarcoma may present explosively, with rapid development of proptosis and decreased visual acuity (18). Craniopharyngiomas may present with advanced visual field defects, with or without headache, and sometimes with an unusual vertical "see-saw" nystagmus. By contrast, optic neuritis (ON) presents with sudden, severe unilateral or bilateral visual loss. There may be a history of an antecedent viral infection. On examination, there is reduced vision, nonreactive pupils, and swollen optic nerves. Hemorrhages and exudates may be seen on the optic disc.

Table 255.5 lists the differential diagnoses of abnormal vision.

TABLE 255.5
Differential Diagnosis of Abnormal Vision[a]

Physical Finding	Age	Differential Diagnosis
Leukocoria	Infant	Cataract
	Older child	Retinoblastoma
	Other tumor	
Tearing	Neonate	Congenital nasal lacrimal duct obstruction
		Glaucoma
Failure to fix or follow	2–3 mos	Abnormal visual development
		Any cause of decreased vision
		Strabismus
Nystagmus	Infant	Benign
	Older child	Any cause of decreased vision
		Tumor
		Amblyopia
		Drug induced
Decreased visual acuity (monocular)	Infant	Cataract
		Glaucoma
		Tumor
		Refractive errors
	Child	Amblyopia
		Refractive errors
		Tumor
		Orbital cellulitis
	Older child	Optic neuritis
	Adolescent	Tumor
		Trauma
		Refractive errors
Decreased visual acuity (binocular)	Variable ages	Glaucoma
		Retinoblastoma
		Optic neuritis
		Refractive errors
		Cortical visual loss
Proptosis	All ages	Rhabdomyosarcoma
		Other tumor
		Retrobulbar infiltrative process
Strabismus	All ages	Amblyopia
		Muscle palsy
		Large unilateral refractive error

[a]This table is intended as a guide to the more common diagnoses and is not comprehensive.

Children with complaints related to vision rarely present to the ED. When they do, the visit is prompted by their own complaints of abnormal vision or complaints from their parents, teachers, or school nurses. Occasionally, the ED physician, during the course of an examination, discovers a particular finding that necessitates urgent ophthalmologic referral. The complaints and etiologies for visual loss can vary greatly with the age of the child.

Nystagmus in childhood may be congenital or acquired. The etiologies of congenital nystagmus are essentially the same as those causing visual impairment in infancy. Nystagmus that develops in the older child is usually either drug-induced or associated with severe visual loss or intracranial neoplasm.

The most common complaint in the toddler and preschool-aged child seen in the primary care office (and, therefore, the pediatric ED as well) is strabismus or ocular malalignment. At birth, most babies display mild exotropia (outward deviation). This neonatal misalignment typically resolves by 3 months of age, and any strabismus after this age is abnormal. Large-angle esotropia (inward deviation) is also abnormal in infants (19).

Cataracts, glaucoma, intraocular tumors, optic nerve problems, and nystagmus may all present in infancy. The incidence of congenital cataracts is 1 to 4 of 10,000 live births in industrialized countries and 5 to 15 of 10,000 births in the developing world. Cataracts usually present in the newborn nursery (20). However, with home births and the easy movement of populations between developing countries and the industrialized world, it is conceivable that the first presentation may be in the ED. Cataracts are strongly associated with several chromosomal abnormalities (trisomy 13, 18, 21), perinatal infections (rubella, toxoplasmosis, or HSV), and inborn errors of metabolism (20).

Primary glaucoma has an incidence of <1 in 10,000 live births in Western countries; certain south Asian populations have up to a ninefold increased incidence related to increased rates of consanguinity in marriage. Most cases present before 6 months of age and 80% within the first year of life. Secondary glaucoma may occur as a result of prior eye surgery, uveitis, or in association with syndromes such as Sturge–Weber. Children with secondary glaucoma can present later than those with primary glaucoma.

Cortical visual impairment, defined as bilateral visual impairment in the presence of normal ocular structures and pupillary light reflex and absence of nystagmus, has increased in the United States in the past decade to become one of the most common causes of childhood blindness. The most common cause is perinatal hypoxia; however,

many other entities such as CNS infections, CNS malformations, epilepsy, malignancy, drugs, and head trauma may result in cortical visual impairment (21).

Retinoblastoma is the most common intraocular malignancy. The average age of presentation is 18 months, with 90% occurring prior to 5 years of age (22). One-third of tumors is bilateral and present earlier than unilateral tumors. The 10% of cases that present in older children are unilateral and not of the familial type (22).

Visual loss in childhood may result from compression of the optic nerve by tumor, inflammation of the optic nerve, and heredodegenerative conditions. Ten percent of rhabdomyosarcomas occur in the eye, arising from the intraocular muscles. The peak incidence is at age 8, with 75% occurring before age 10. Optic Neuritis (ON) in the child may be a postviral autoimmune phenomenon. The most common preceding infections are measles, mumps, varicella, pertussis, mononucleosis. Optic neuropathy has been reported in a few children with Lyme disease. Until recently, it was felt there was a weak association in children between ON and multiple sclerosis (MS). However, a recent small study showed that children with unilateral ON had a 36% progression rate within 2 years to MS. The presence of extraocular white matter lesions on MRI, bilateral ON, and extraocular clinical findings led to higher rates of MS diagnosis (11).

Optic gliomas and craniopharyngiomas are the two most common tumors that compress the optic nerve. Optic gliomas are intrinsic tumors of the optic nerve. They usually occur between 4 and 8 years of age. There is a strong association with neurofibromatosis. Craniopharyngiomas are the third most common brain tumor of childhood, representing 10% of all tumors in childhood. They arise from the embryonic rests of Rathke pouch near the sella turcica. Craniopharyngiomas affect visual acuity by compressing the optic chiasm or the optic nerve (22).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for visual disturbance includes, cataracts, glaucoma (either primary or secondary), intraocular tumors,

nystagmus, or ON (Table 255.5).

ED EVALUATION

When a tumor is suspected, neuroimaging, beginning with a CT scan, is imperative. Particularly, any finding of proptosis, with or without decreased vision, necessitates an urgent CT scan or MRI. The evaluation of ON includes magnetic resonance imaging and an LP. The LP usually reveals a monoclonal pleocytosis and mild protein elevation.

KEY TESTING

- CT scan if tumor is suspected
- MRI and LP if ON is suspected

ED MANAGEMENT

The emphasis in management, in the majority of these conditions, should be on recognition of the potential severity of the problem; timely neuroimaging, when applicable; and prompt, sometimes emergent, referral. Surgery is the mainstay of treatment for glaucoma, but medications such as pilocarpine or a β-blocker are often used initially to control intraocular pressure while awaiting surgery.

Therapy for ON is based on randomized clinical trials conducted in adults. The optic neuritis treatment trial (ONTT) demonstrated that IV steroids resulted in a more rapid improvement in vision, a benefit that waned at 12 months. There was, however, a significant reduction in progression in adults to multiple sclerosis at 2 years, but this effect was lost at 5 years. Oral steroids (prednisone) alone were conclusively shown to be detrimental. The decision to treat with IV steroids remains somewhat controversial but is frequently offered by ophthalmologists to children with bilateral disease because of a worse prognosis for visual recovery. The steroid therapy of choice is methylprednisolone 15 to 30 mg/kg/d for 10 to 14 days. This is followed by a slow prednisone taper over 1 to 2 months. Too rapid a taper has been associated with a recurrence of ON and compounded

visual loss. In spite of severe initial visual deficits, 80% of children had excellent visual recovery.

The treatment of cataracts, tumors, or glaucoma is largely surgical. Because infancy, particularly the first 2 months of life, represents a critical period in normal visual maturation, failure to remove the obstruction to clear vision could result in irreversible amblyopia, a functionally blind eye or difficulties with stereoscopic vision (19).

DISPOSITION

Tumors, glaucoma, cataracts, and ON often involve urgent admission to the hospital. The facility, as well as the consultant, should be experienced in pediatric eye disorders. Because the growth of some tumors, such as rhabdomyosarcoma, can be explosive, consultation with an experienced ophthalmologist is emergent.

The presence, in an infant, of leukocoria or a swollen anterior chamber requires urgent referral to an ophthalmologist comfortable with the treatment of pediatric cataracts, tumors, and glaucoma.

Because nystagmus can represent a structural lesion as well as amblyopia, there should be referral to an ophthalmologist on a semiurgent basis.

The finding of strabismus in the preverbal or preschool child mandates outpatient referral to an ophthalmologist.

Children with known risk factors for secondary glaucoma should undergo periodic routine ophthalmic evaluation.

Common Pitfalls

- Failure to perform an age-appropriate, complete eye examination.
- Failure to refer a time-dependent process urgently to an appropriate ophthalmologist.

NASOLACRIMAL DUCT OBSTRUCTION AND DACRYOCYSTITIS

CLINICAL PRESENTATION

Congenital nasolacrimal duct obstruction (CNLDO) is a common problem of infancy, with 20% of children exhibiting some symptoms within the first year of life. Canalization of the nasolacrimal duct may not be complete at birth. In most of these children, a membranous obstruction is the etiologic factor; however, a nasolacrimal duct cyst may also result in obstruction (23). Ninety-six percent of infants with CNLDO show spontaneous resolution of the obstruction by the first birthday. Refer to Figure 255.2 for anatomy of the nasolacrimal duct.

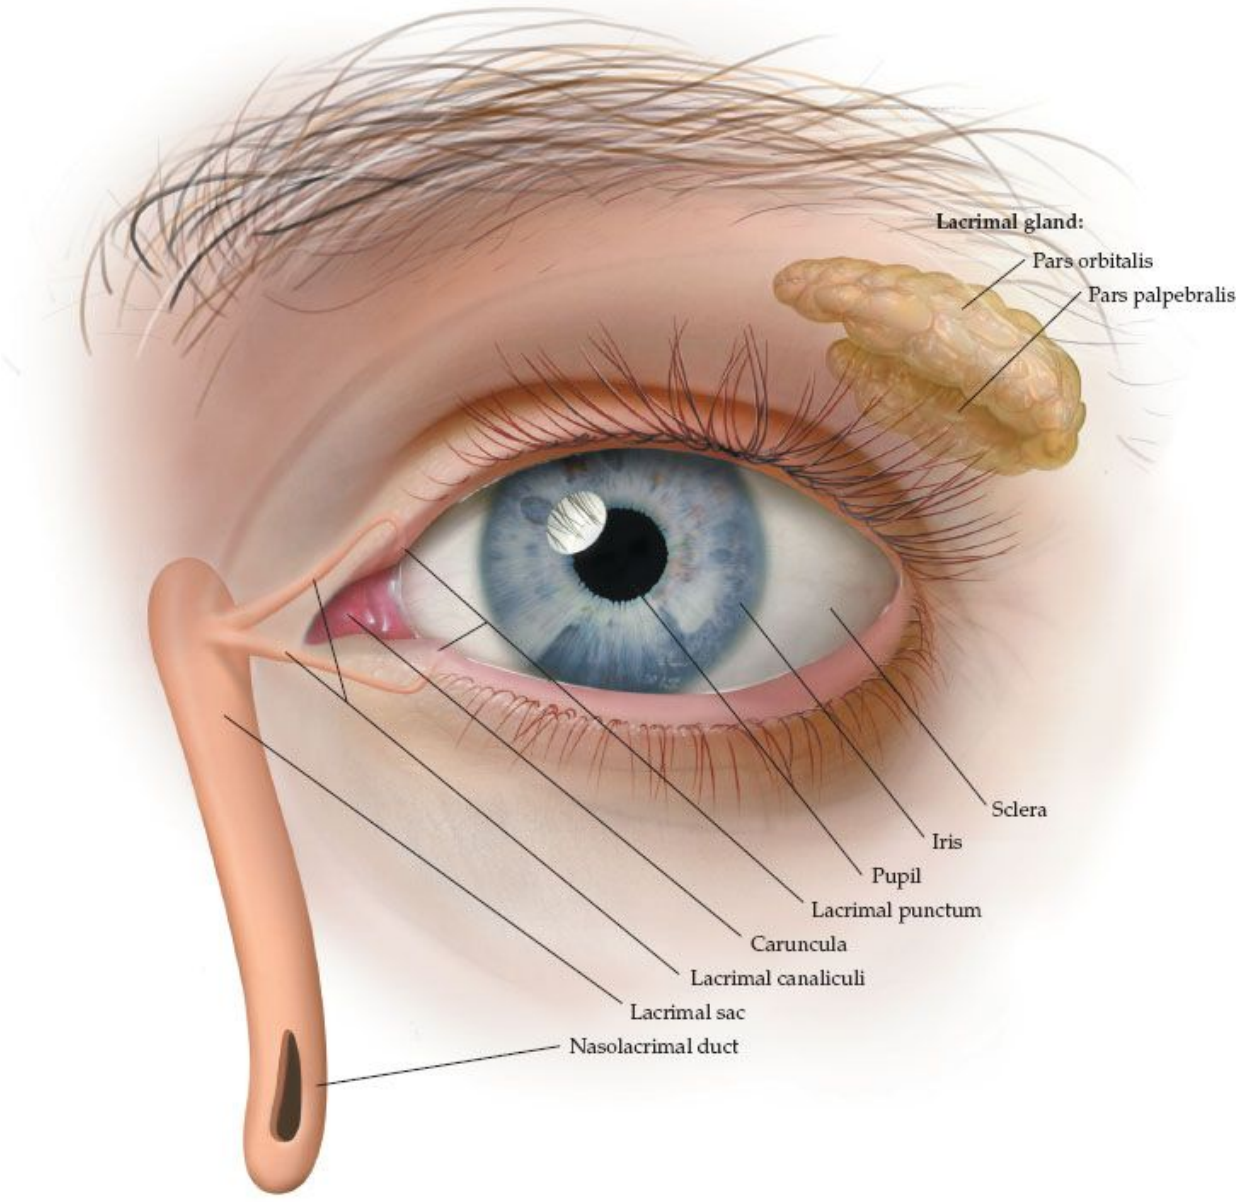

FIGURE 255.2 Eye anatomy; left eye outer labeled. (Asset courtesy of Anatomical Chart Company, ©2014.)

Dacryocystitis, or infection of the nasolacrimal duct, may be acute or chronic. It may occur as a complication of CNLDO or of acquired nasolacrimal duct obstruction (ANLDO). In the neonatal period, dacryocystitis is rare, occurring in <2% of infants with CNLDO. However, if a duct cyst is the etiology of the obstruction, the risk of dacryocystitis is greater, with earlier presentation, usually by 2 weeks of age (23). The causative organisms are most often *S. aureus, Staphylococcus epidermidis,* and α-hemolytic streptococci. *Corynebacterium diphtheriae* and Epstein–Barr virus have also been reported (24). The risk of bacteremia is higher in the neonatal period than in the older infant or child. ANLDO may occur as the result of ethmoidal sinusitis or maxillary fracture through the wall of the nasolacrimal duct (24).

Symptoms of CNLDO may be present at birth or may be delayed for several weeks, until normal tear production develops. Signs include excessive tear lake, tear overflow, or a mucoid discharge that is produced by the lacrimal sac. The tearing is often distressing to the parent. There may be crusting or stickiness of the eye; however, the conjunctivae are clear, the eye is neither red nor swollen and the patient should not be febrile.

Dacryocystitis is characterized by erythematous and swollen skin over the lacrimal sac and purulent drainage from the punctum. Fever may be present and POC or OC may develop as a complication of dacryocystitis (24).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for dacryocystitis includes corneal abrasion, local trauma with infection (i.e., insect bite), conjunctivitis, and in advanced cases OC or POC.

ED EVALUATION

A careful history and physical examination should differentiate CNLDO from dacryocystitis. In the latter case, cultures of any purulent drainage, as well as blood cultures, need to be obtained. A complete blood count may be helpful, with a high white blood cell count indicating a higher risk of bacteremia. In the infant who is 1-month old or younger, a full sepsis workup, including lumbar puncture, should be done.

KEY TESTING

- Culture of drainage and blood cultures
- Full sepsis workup in the infant less than 1 month of age

ED MANAGEMENT

In dacryocystitis, antibiotics to cover *Staphylococcus* and *Streptococcus* species should be started immediately after cultures are obtained. The choice of particular antibiotics should reflect *Staphylococcus* and *Streptococcus* resistance and the increase in MRSA within each community

Recommended agents include:

- Clindamycin 40 mg/kg/d IV in three or four divided doses
- Nafcillin 150 mg/kg/d IV doses
- Cefuroxime 150 mg/kg/d IV in three divided doses

In the penicillin-allergic infant or child, vancomycin can be used (5).

DISPOSITION

All patients with acute dacryocystitis should be admitted to the hospital due to the potential complications of sepsis and/or meningitis. Immediate consultation with an ophthalmologist is required, because early nasolacrimal duct probing is important for successful treatment of acute dacryocystitis. Because neonatal dacryocystitis is often associated with a nasolacrimal duct cyst, a complete intranasal examination at the time of surgery and marsupialization of any cyst is imperative to prevent recurrence (23).

The treatment of chronic or “low-grade” dacryocystitis is primarily surgical, with duct probing within several weeks of presentation. Systemic antibiotics are not necessary, although some consultants recommend a topical antibiotic ointment such as polymyxin B (23).

Dacryocystitis after facial fracture or sinusitis requires referral to the appropriate specialist: ophthalmology, otolaryngology, or plastic surgery (23).

Conservative management of CNLDO includes warm water compresses (to remove the mucoid discharge) and nasolacrimal duct massage; performed by occluding the common canaliculus with the index finger and then stroking firmly downward. This maneuver increases the hydrostatic pressure in the nasolacrimal sac, with the ultimate goal of overcoming the membranous obstruction. Massage the duct in repetitions of 5 to 10 passes, 4 to 6 times a day is recommended. Erythromycin ophthalmic ointment applied 4 times a day is also recommended; however, its efficacy in speeding recovery is not proven. Referral to an ophthalmologist is recommended for cases that do not resolve with conservative management. Probing will cure 90% of these infants (23). Newer, minimally invasive techniques such as balloon dacryocystoplasty, lacrimal stents, conjunctivoplasty, and endoscopic dacryocystorhinostomy are continually being refined and may be offered in individual cases.

Common Pitfalls

- Failure to consider bacteremia, sepsis, or meningitis in the neonate or young infant.
- Failure to consult an ophthalmologist early in cases of acute dacryocystitis.

CHAPTER 256

Ear Infections

Elizabeth L. Thorpe and Melissa A. Vitale

Earache can be caused by infections or can result from referred pain from pharyngitis, odontogenic pain, external otitis, parotitis, or a foreign body in the ear canal. Infections of the ear can involve the middle ear (otitis media) and mastoid air cell system (mastoiditis), as well as the outer ear (otitis externa [OE]).

ACUTE OTITIS MEDIA

Acute otitis media (AOM) is the most common reason for antibiotic prescriptions in children, and a leading cause of acute care visits (1). Young children are prone to develop AOM secondary to their eustachian tube (ET) anatomy (short, narrow, horizontal, and floppy) and their frequent viral upper respiratory infections (URIs). URIs cause ET dysfunction via inflammation and consequent edema as well as decreased ciliary activity. This prevents physiologic drainage of middle ear secretions into the nasopharynx, and creates a negative pressure that draws bacteria from the nasopharynx into the middle ear. Accordingly, AOM is most commonly diagnosed in children less than 2 years of age, especially in those who attend daycare and experience frequent URIs. Other risk factors include smoke exposure, lack of breast-feeding in the first 6 months of life, pacifier use beyond the first 6 months of age, and craniofacial anomalies (e.g., Down syndrome, cleft palate).

The most common pathogens are *Streptococcus pneumoniae* and nontypeable *Haemophilus influenzae* followed by *Moraxella catarrhalis.* Since the introduction of the heptavalent pneumococcal conjugate vaccine (PCV-7), the microbiology of AOM has shifted toward a

predominance of *H. influenzae* and non-PCV-7 strains of *S. pneumoniae* (2,3). While the proportion of penicillin (PCN)-resistant *S. pneumoniae* and beta-lactamase–positive *H. influenzae* has remained stable in children with first-time AOM, there has been a notable increase in resistant strains in children with treatment failures or recurrent AOM (2). Several highly resistant serotypes of *S. pneumoniae* (19 A, 7 F, 6 C) that are not included in PCV-7 have emerged as major pathogens causing the incidence of *S. pneumoniae* to be comparable to pre-PCV-7 rates (2). In 2010, the 13-valent pneumococcal conjugate vaccine (PCV-13) was introduced. Preliminary studies of nasopharyngeal carriage rates in children less than 2 years of age with AOM who received PCV-13 showed a marked decrease in the prevalence of serotypes 19 A, 7 F, and 6 C (4). Viruses also cause AOM and may be clinically indistinguishable from bacterial AOM; common viral etiologies include picornavirus, respiratory syncytial virus, and enterovirus. Of note, infants under 8 weeks of age with AOM most often have the typical pathogens, but can also have Group B *streptococcus* and gram-negative bacilli (5). In children with tympanostomy tubes, *Staphylococcus aureus* and *Pseudomonas aeruginosa* are also common, with methicillin-resistant *S. aureus* becoming more prevalent (6).

CLINICAL PRESENTATION

The symptoms of AOM have an acute onset, usually within 48 hours of clinical presentation, and include otalgia, fever, excessive crying or fussiness, restless sleep, and decreased appetite. Otalgia has the highest likelihood ratio in predicting the presence of AOM (3). In nonverbal children, otalgia may be indicated by tugging or rubbing the ear. The absence of fever does not rule out AOM and in fact, studies have demonstrated that presence of fever cannot predict the diagnosis of AOM (7).

DIFFERENTIAL DIAGNOSIS

When AOM is not present, the most likely cause of otalgia is referred pain from infection or trauma in regions with shared innervation, namely the pharynx, nares, and teeth. ET dysfunction causing

negative pressure and temporal–mandibular joint pathology can also cause otalgia.

ED EVALUATION

In an attempt to increase the diagnostic accuracy of AOM as well as decrease the unnecessary use of antibiotics, guidelines have been published and most recently revised in 2013 (8). According to these guidelines, AOM is diagnosed if the tympanic membrane (TM) is bulging severely or moderately, indicating a middle ear effusion (MEE), *or* there is new onset of otorrhea not due to OE (8). AOM can also be diagnosed if there is mild bulging of the TM *and* onset of ear pain within the last 48 hours or intense erythema of the TM (8). In the absence of a MEE, AOM cannot be diagnosed.

Examination of the TM is facilitated by using the largest speculum that fits comfortably in the canal to allow proper visualization. Pneumatic otoscopy involves assessing TM mobility by insufflating air into the external ear canal. This technique can aid in confirming the presence of a MEE, in which case the TM is not mobile; however, this will not be successful as a diagnostic test unless the speculum forms a tight seal on the ear canal. If the TM cannot be visualized because of cerumen, the cerumen can be removed with a curette or by gentle irrigation with warm water. Cerumenolytics can be instilled before irrigation. MEE can signify either AOM or otitis media with effusion (OME); it is the presence of inflammatory changes that distinguishes AOM from OME. A red TM and the acute onset of otalgia that interferes with a child's normal activities are consistent with inflammation of the middle ear. It is important to note that although redness of the TM can represent inflammation, it can also be secondary to vascular engorgement caused by fever or crying. Relying on TM redness alone will result in the overdiagnosis of AOM. This finding, combined with the acute onset of symptoms and evidence of MEE on examination is more specific for AOM.

It is important to assess for complications of AOM on physical examination by including the mastoid process and cranial nerves (refer to Chapter 68). A cholesteatoma (a white cystic mass behind or involving the TM) can develop within the middle ear, leading to a

facial nerve palsy secondary to inflammation of the facial nerve as it traverses the inner and middle ear.

Adjunctive Diagnostics

Tympanocentesis, needle aspiration of MEE, is useful to establish a bacterial diagnosis. It should be considered in neonates and patients with immunosuppression, persistent treatment failure and/or suppurative complications (1). This is most commonly performed by an otolaryngologist.

KEY TESTING

- No specific diagnostic tests are generally indicated.

ED MANAGEMENT

The primary goals of treatment are to relieve symptoms and prevent complications. Appropriate management decisions are based upon the child's age, allergies, recent antibiotic exposure, and the severity of the infection. Refer to Table 256.1 for drug dosages. Febrile or irritable neonates require hospitalization for parenteral antibiotics. In the rare circumstance that a cranial nerve palsy is present, an emergent myringotomy should be performed by an otolaryngologist.

TABLE 256.1
Oral Antibiotic Treatment Options for AOM

Antibiotic	Dosage
High-dose amoxicillin[a]	90 mg/kg/d divided BID
High-dose amoxicillin–clavulanate[b]	90 mg/kg/d divided bid based on amoxicillin component, using ES preparation
Cefuroxime	30 mg/kg/d divided bid
Cefpodoxime	10 mg/kg/d divided qd or bid
Cefdinir	
Ceftriaxone[c]	14 mg/kg/d divided qd or bid
50 mg/kg /d IM or IV for 3 d	

Standard duration of therapy is 10 days. For those older than 6 years who have nonsevere illness, a 5–7-day course is acceptable (1).
[a]Recommended first-line treatment.
[b]Treatment after 48–72 hours of initial antibiotic if symptoms fail to improve.

Pain Management

Pain from AOM may be significant in the first few days of infection, and therefore it is important to manage in the emergency department (ED). Studies have shown that children less than 2 may have pain for longer periods than older children with AOM, even extending up to 3 to 7 days after initiating antibiotics (9). Oral analgesics such as ibuprofen and acetaminophen are effective in controlling pain from AOM and should be initiated even if antibiotics are not started (8). In rare cases, opioids may be needed. There is not sufficient evidence to support the routine use of topical analgesics (8). If used, they should only be utilized in the presence of an intact TM. Other adjunctive medications, namely decongestants, antihistamines, and systemic steroids, are not beneficial and are associated with increased side effects.

Decision for Antibiotics

The decision to treat a child with antibiotics is based on the child's age and severity of symptoms (Fig. 256.1). For children age 6 to 24 months, antibiotics should be initiated for AOM with otorrhea, bilateral AOM, or AOM with severe symptoms (defined as toxic appearance, otalgia for more than 48 hours, temperature of 39°C or above in the past 48 hours, or uncertain access to a follow-up visit) (8). For a certain diagnosis of unilateral AOM without severe

symptoms, antibiotics may be started, or watchful waiting may be used (see below). For children **older than 24 months,** antibiotics are recommended for AOM with otorrhea or AOM with severe symptoms (8). For unilateral or bilateral AOM without severe symptoms, either antibiotics or watchful waiting may be utilized. For children **less than 6 months,** antibiotics should be initiated for AOM. However, it is important to also evaluate for alternative sources of infection in the urine, blood, and potentially the CSF, if fever is present in this age group.

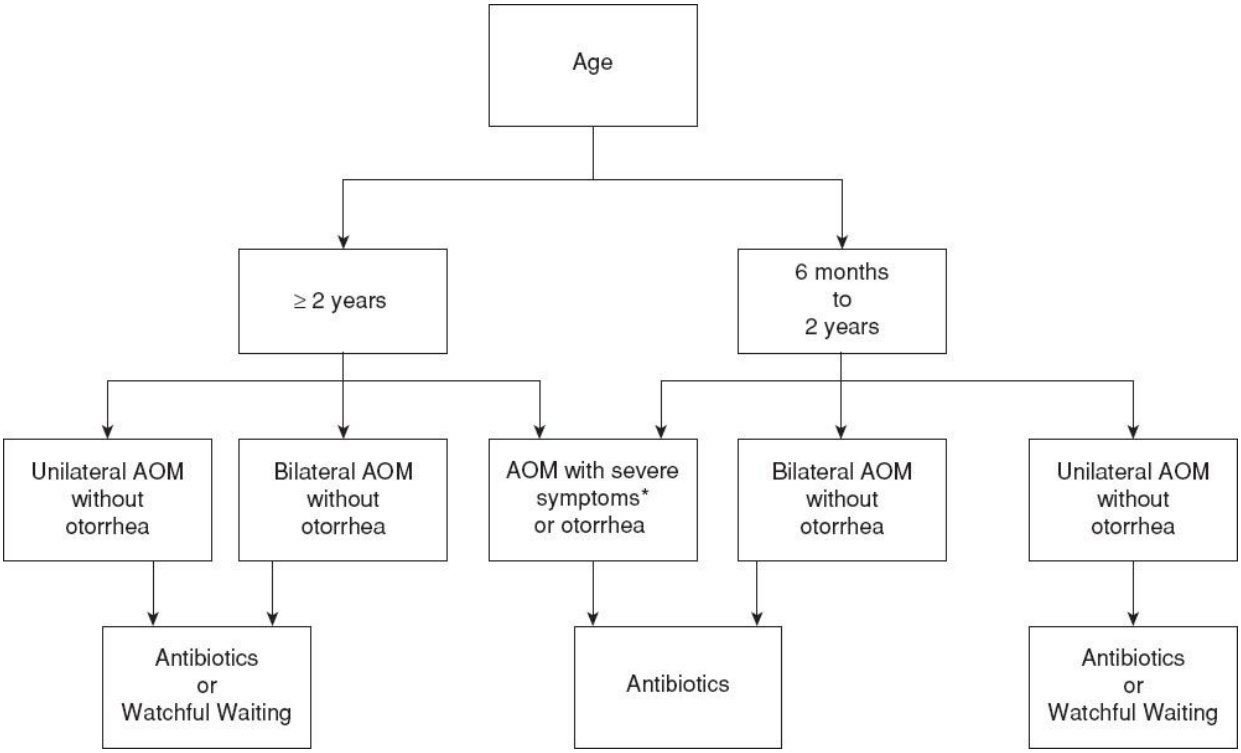

FIGURE 256.1 Algorithm for Management of Acute Otitis Media. *Severe symptoms are defined as toxic appearance, otalgia for more than 48 hours, temperature of 39°C or above in the past 48 hours, or uncertain access to a follow-up visit.

A management strategy of "watchful waiting" with the avoidance of antibiotics for certain patient populations initially gained support in the United States in the early 2000s. When compared to those who successfully avoided antibiotics with watchful waiting, patients treated with antibiotics had higher rates of multidrug-resistant

pathogens, and suffered more antibiotic sides effects, most notably diarrhea (10). In addition to decreasing bacterial resistance, proponents also sited the high rate of spontaneous resolution of bacterial AOM. If the "watchful waiting" strategy is chosen, follow-up must be assured and antibiotics must be able to be initiated if symptoms worsen or fail to improve within 48 to 72 hours. In the ED setting, this may be facilitated by giving the parents a prescription to hold for 2 to 3 days that is filled if symptoms are not improved over this time period. If follow-up cannot be assured, the "watchful waiting" strategy should not be utilized (8).

Antimicrobial Therapy

Because *S. pneumoniae* and *H. influenzae* remain the most common pathogens in first-time AOM, initial therapy is directed at these organisms. High-dose (HD) amoxicillin (90 mg/kg/d divided bid; Table 256.1) is the first-line agent in treating AOM (8). In addition, amoxicillin is relatively inexpensive, and tolerated well by children in regards to taste and side effects. For children that have had amoxicillin within the past 30 days, have purulent conjunctivitis on examination, or have a history of recurrent AOM that did not respond to amoxicillin, additional beta-lactamase coverage is needed and HD amoxicillin–clavulanate is the recommended initial agent (8). HD amoxicillin–clavulanate is an ES (extra strength) preparation which allows HD amoxicillin dosing (90 mg/kg/d based on the amoxicillin component, divided bid) while keeping the clavulanate portion in a range less likely to cause diarrhea and other side effects. HD amoxicillin–clavulanate is preferred for patients with concomitant conjunctivitis because of the association of nontypeable *H. influenzae* with conjunctivitis–otitis (11). For patients with a penicillin allergy, reasonable first-line choices include cephalosporins (Table 256.1).

Most children treated for AOM will not feel significantly better within the first 24 hours of treatment. However, if signs and symptoms fail to improve after 48 to 72 hours, second-line therapy should be started (8). Second-line therapy should take into consideration the spectrum of the "failed" antibiotic in order to

provide coverage against the most likely organism(s) untreated by this regimen. Treatment failure with HD amoxicillin suggests beta-lactamase producing organisms; thus, options include HD amoxicillin–clavulanate, select second-generation cephalosporins and ceftriaxone (Table 256.1) (8). Of these oral agents, HD amoxicillin–clavulanate is preferred because it is more biologically potent than the second-generation cephalosporins and proven highly effective against both beta-lactamase producing pathogens as well as penicillin nonsusceptible *S. pneumoniae* (12). Although a single injection of ceftriaxone (50 mg/kg IM) can be used for first-line therapy in patients who are vomiting or who cannot take oral antibiotics, a three-dose (3-day) regimen is recommended if the AOM was unresponsive to initial antibiotic therapy (8). For resistant AOM, some experts recommend a dose of 75 mg/kg of ceftriaxone followed in 48 hours by a second dose of 75 mg/kg. While no specific clinical trials have been conducted using tympanocentesis to document eradication, this regimen is supported by the pharmacokinetics and pharmacodynamics of ceftriaxone (13).

Children with AOM and otorrhea secondary to acute TM perforation are managed similarly to patients without a perforation. However, some clinicians advocate the concomitant use of ototopical agents to hasten the resolution of AOM and prevent the development of OE (14). Because the perforation may seal before sterilization of the middle ear, topical agents cannot be used as monotherapy.

There is no standard therapy for children with tympanostomy tubes and otorrhea from AOM. Monotherapy with topical agents, specifically ciprofloxacin–dexamethasone, is as effective as systemic agents for the typical pathogens and is also effective for *P. aeruginosa,* a common pathogen in this setting for which no oral systemic antibiotic is approved for children (15). Studies have shown that topical ciprofloxacin–dexamethasone compared to oral antibiotics results in more rapid resolution of symptoms (15). Moreover, topical agents do not lead to bacterial resistance, have fewer side effects, and are more convenient for the patient compared with systemic therapy. Ciprofloxacin–dexamethasone dosing for AOM with tympanostomy tubes is the same as for OE (Table 256.2),

four drops twice daily for 7 days. However, ofloxacin dosing for AOM with tympanostomy tubes differs and should be dosed as five drops instilled twice a day for 10 days. Pumping the tragus after the installation of ear drops can improve delivery through the tube. Concomitant treatment with systemic antibiotics is advocated by some clinicians for those children with systemic signs and symptoms or with copious exudate that may interfere with the administration of topical agents. In these cases, use of an agent with additional staphylococcal coverage, such as HD amoxicillin–clavulanate, is useful as *S. aureus* is common in those with chronic drainage. Although routine culture of otorrhea is unnecessary, careful culturing with appropriately sized swabs after cleaning the ear canal can be helpful in those with persistent infection.

TABLE 256.2
Ototopical Antibiotics for Treatment of Otitis Externa

Antibiotic	Product Name(s)	Antiseptic	Acid	Steroid	Dose	Duration
Polymyxin B/neomycin	Cortisporin suspension	+	–	+	3 gtts tid–qid	10 d
	Pediotic	+	–	+	3 gtts tid–qid	10 d
	Cortisporin solution	+	+	+	3 gtts tid–qid	10 d
Ofloxacin	Floxin otic	+	+	–	1–12 yrs: 5 gtts qd	7 d
					>12 yrs: 10 gtts qd	7 d
Ciprofloxacin and dexamethasone	Ciprodex	+	+	+	4 gtts bid	7 d

DISPOSITION

If no evidence of serious systemic infection is present, children may be managed as outpatients. A follow-up appointment with the primary care physician should occur in 2 to 3 weeks to monitor recovery of the MEE. Instruction should be given for patients to seek care sooner if symptoms, including fever, do not resolve in 48 to 72 hours or signs of worsening infection develop. Children with toxicity, other serious systemic infections, intracranial complications, or clinically significant immunodeficiencies and febrile neonates should be hospitalized and placed on parenteral antibiotics.

Common Pitfalls

- Overdiagnosis of AOM secondary to failure to remove cerumen from ear canal.
- Diagnosis based solely upon redness of the TM.
- Failure to distinguish OME from AOM.
- Failure to consider other more serious coexisting diagnosis, such as sepsis or meningitis.

MASTOIDITIS

Mastoiditis is a suppurative complication of AOM. It most commonly affects children less than 2 years of age, but can be seen in all age groups. The overall incidence of mastoiditis has decreased since the introduction of antibiotics for the treatment of AOM. Mastoiditis is a spectrum of disease ranging from infectious inflammation of mastoid air cells to abscess development and subsequent spread to contiguous areas. The most common bacterial pathogens are *S. pneumoniae* and *Streptococcus pyogenes,* followed by *S. aureus, P. aeruginosa, and* nontypeable *H. influenzae.* In the post-PCV-7 era, *S. pneumoniae* remains the predominant pathogen with serotype 19 A and other drug-resistant serotypes becoming increasingly common (16).

CLINICAL PRESENTATION

Acute mastoiditis (AM) represents a spectrum of disease**. AM without periostitis or osteitis** is the initial subclinical stage involving inflammation of the lining of the mastoid air cells. Because the mastoid is directly connected to the middle ear, almost all episodes of AOM are thought to be associated with some inflammation of the mastoid. Diagnosis of this stage is often made incidentally when cranial imaging, obtained for other reasons, reveals cloudy mastoids without evidence of bony erosion. There are no specific clinical signs or symptoms of mastoiditis in this stage, and no special treatment is required.

AM with periosteitis occurs when the infection spreads into the periosteum. Patients present clinically with postauricular edema, erythema, and tenderness. The postauricular crease may be absent. The auricle may be displaced downward and outward. Fever, ear

pain, and irritability are common, especially in younger children. Up to half of children presenting with mastoiditis may not have had AOM diagnosed within the preceding weeks (17). This may occur when a middle ear infection resolves but granulation tissue or edema obstruct the narrow tube connecting the middle ear to the mastoid thus preventing drainage and resolution of the mastoiditis. In addition, studies have demonstrated that up to half of patients with mastoiditis were treated prior with antibiotics for AOM (17,18), suggesting that appropriate treatment of AOM may not prevent the development of mastoiditis. Most importantly, since the introduction of AOM "watchful waiting" guidelines in 2004, no significant increase in the incidence of AM has been noted (18).

AM with osteitis occurs when the infection results in erosion of the bony septae that separate the mastoid air cells, resulting in an empyema; making some children appear toxic. Infection can spread laterally creating a postauricular subperiosteal abscess, anteriorly creating a preauricular abscess, inferiorly toward the sternocleidomastoid muscle, medially into the petrous air cells and inner ear labyrinth, or posteriorly into the calvarium.

Chronic mastoiditis is most commonly a manifestation of chronic suppurative otitis media (otitis with perforation and persistent otorrhea) that has failed outpatient therapy. However, it can occur in a child with ineffectively treated AM.

Differential Diagnosis

The differential diagnosis of AM includes OE with postauricular cellulitis, perichondritis of the pinna, and postauricular lymphadenitis. In each of these, middle ear disease is usually absent, and with perichondritis of the pinna and postauricular lymphadenitis, the posterior auricular crease usually remains intact. Postauricular lymphadenitis is usually seen in the presence of scalp infection or inflammation.

ED EVALUATION

If symptoms and signs of mastoiditis are present, a CT scan of the temporal bones should be performed. Key findings of mastoiditis are destruction and coalescence of the mastoid air cells. Historically, a head CT was not recommended unless signs and symptoms of intracranial complications were present. However more recently, a case series of 70 patients with AM showed that of 10 patients with intracranial complications (parasinus empyema, sigmoid sinus thrombosis, epidural abscess, and subdural abscess), none had neurologic signs or symptoms on presentation. This suggests that a head CT with contrast should strongly be considered in all patients presenting with suspected AM (19).

KEY TESTING

- CT scan of the mastoid bone
- CBC
- Palpation of the mastoids to check for tenderness.

ED MANAGEMENT

It is recommended that all patients with mastoiditis be admitted for treatment (20). However, some clinicians will advocate an attempt at outpatient treatment in mild cases when close follow-up can be assured. HD amoxicillin–clavulanate will treat the most common pathogens, with the exception of *P. aeruginosa.* Fluoroquinolones are relatively contraindicated in young children because of theoretic, but unproven, concerns about cartilage toxicity. When *P. aeruginosa* is suspected, tympanocentesis can be helpful in directing therapy. Any patient with AM presenting with fever, ill appearance or osteitis should be admitted for parenteral antibiotics and otolaryngology consultation (20). Traditional treatment involved intravenous antibiotics and mastoidectomy with the removal of necrotic bone. More recently, the use of myringotomy with or without the placement of tympanostomy tubes has obviated the need for mastoidectomy in many cases. Serial CT scans are used to document resolution of infection. Ampicillin–sulbactam or third-generation cephalosporins are acceptable for initial intravenous antibiotic

therapy. In the post-PCV7 era, the resistance of *S. pneumoniae* to both PCN and ceftriaxone is increasing and therefore some have suggested empiric treatment with both ceftriaxone and clindamycin (16). For patients who have proven ceftriaxone-resistant *S. pneumoniae* or in those for which there is a high index of suspicion, vancomycin can be added. If *P. aeruginosa* is suspected, initial, empiric antipseudomonal coverage with ceftazidime or piperacillin–tazobactam can be used. Subsequent therapy can be modified based upon culture results from tympanocentesis.

Chronic mastoiditis may be treated with a parenteral antipseudomonal antibiotic. Otolaryngology consultation is advised as mastoidectomy is necessary for patients that do not improve with medical management.

DISPOSITION

Patients with early, mild cases of AM with periosteitis may be managed as outpatients using antibiotic therapy combined with close follow-up. All other cases require hospital admission, parenteral antibiotics, and otolaryngology consultation.

Common Pitfalls

- Failure to recognize AM or distinguish AM from OE with cellulitis, perichondritis of the pinna or postauricular lymphadenitis.
- Failure to consider concurrent intracranial complications of AM such as meningitis and brain abscess.

OTITIS EXTERNA

OE is a diffuse inflammation or infection of the external ear canal which is most often acute in nature (refer to Chapter 68). Although swimming is the most common precipitant, a break in the epithelial lining from any cause (e.g., trauma, foreign body, and eczematous skin disorder) can result in OE. The lifetime incidence of OE is 10% and peaks between the ages of 7 and 12 years; it is rare in those less than 2 years (21). The most common bacterial pathogen is *P. aeruginosa* followed by *S. aureus*. Fungal OE (*Candida and Aspergillus*

species) is rare in the United States and occurs more often in cases of chronic OE and refractory infection (22).

CLINICAL PRESENTATION

The diagnosis of OE is consistent with a history of rapid onset of symptoms over 48 hours, including otalgia, otorrhea, pruritus, and sense of ear fullness. Additional but less common symptoms include hearing loss or jaw pain. The infection may spread to the surrounding soft tissue resulting in a periauricular cellulitis and perichondritis. Bone infections can occur with spread to the mastoid or cranium. Necrotizing (malignant) OE is a rare, but aggressive infection (usually caused by *Pseudomonas* species) may be potentiate systemic spread (refer to Chapter 68).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes middle ear infections, other external ear canal disorders (furunculosis, herpes zoster oticus) and mastoiditis. OE and AOM can often be distinguished clinically by the presence or absence of pain with manipulation of the outer ear. However, if an episode of AOM is complicated by TM perforation, the purulent drainage can cause a secondary OE. *Furunculosis* is caused by an infected hair follicle in the distal portion of the external canal causing a localized OE. This condition responds well to drainage and antistaphylococcal antibiotics. Ramsay Hunt syndrome is a *Herpes zoster* infection in the distribution of the facial nerve presents with vesicles in the external auditory canal or auricle, facial nerve paralysis, hearing loss, and vertigo. Finally, *mastoiditis* may be difficult to distinguish from OE with postauricular cellulitis, and may require diagnostic imaging to clarify the diagnosis. Loss of the postauricular fold and tenderness over the mastoid are more common in mastoiditis.

ED EVALUATION

The diagnosis of OE is based on history and physical examination. Key examination findings are tenderness elicited by manipulation of the tragus or pinna and diffuse ear canal edema or erythema (21).

Canal wall edema may progress to obstruction, trapping debris and secretions in the proximal canal and preventing visualization of the TM (refer to Chapter 68).

KEY TESTING

- Careful physical examination, looking for purulent discharge and manipulation of tragus or pinna to elicit pain

ED MANAGEMENT

Management of OE consists of controlling inflammation and infection; thus, it is important for the appropriate topical otic agents to reach the inflamed, edematous canal. In mild OE, secretions can be dry mopped with rolled tissue or swabs prior to antibiotic administration. In severe OE with near-obstruction of the canal, a wick made of compressed cellulose or gauze can be inserted. The topical antibiotic is then dripped onto the absorbent wick allowing delivery of the medication to the obstructed portion of the canal. If the wick does not fall out on its own as the canal edema decreases, it should be removed in 2 to 3 days. In the absence of an ear wick, the topical antibiotic should be instilled in the outer ear canal while the patient is lying with the affected side up. Medication delivery is enhanced by gently moving the pinna to and fro. The patient should remain on their side for 3 to 5 minutes. The canal may be then left open (21).

Topical antibiotics are recommended as first-line treatment for uncomplicated OE (21). Oral antibiotics are reserved for immunocompromised hosts and cases where infection extends beyond the external ear canal, including concomitant AOM. Classes of ototopicals currently used to treat OE include acidifying agents, antiseptics, antibiotics, and steroids. Topical acidic solutions inhibit bacterial growth, but are not commonly used because they cause local burning and irritation. Topical antimicrobials aimed at treating the leading causative organisms (*P. aeruginosa* and *Staphylococcus spp*) are the mainstay of therapy (Table 256.2). Polymyxin B–neomycin–hydrocortisone agents have been used extensively for

years with good results; however, they have been associated with hypersensitivity and ototoxicity and should be avoided if the TM is perforated. Topical fluoroquinolones (ofloxacin and ciprofloxacin) are now used more commonly due to a decreased risk of ototoxicity and hypersensitivity. Newer research also shows that quinolones may be superior to traditional agents regarding both bacterial eradication and cure of OE (23). The two fluoroquinolones differ in that the ciprofloxacin preparation contains dexamethasone whereas the ofloxacin preparation does not. Fluoroquinolones are the only topical agents approved in OE with TM perforation. Studies comparing topical antibiotics with and without a steroid have shown comparable clinical cure rates (24). Fungal OE treatment involves cleansing with acidifying agents (2% acetic acid or 90% alcohol solution); antifungal drops are reserved for severe infections (25). Eczematous OE treatment is the same as for the primary disorder.

DISPOSITION

In the absence of an accompanying cellulitis with systemic symptoms, children can be managed at home. Reevaluation should occur if symptoms do not improve in 48 to 72 hours. Follow-up is also recommended in severe cases when complete examination of the external canal and TM is not possible or when an ear wick is placed. Patients should be advised to abstain from swimming for 7 to 10 days during treatment; hearing aids should not be inserted until pain and otorrhea has resolved (21). Prophylaxis against recurrent swimmer's ear includes application of drops containing equal parts vinegar and alcohol (to alter pH and dry the canal, respectively) immediately after swimming. A hairdryer set on low and held one foot from the ear can also be used to dry the ear canal after swimming. The use of earplugs for prevention of OE is controversial. Earplugs will keep the canal dry only when properly fitted and may cause local irritation and impaction of debris/cerumen.

CRITICAL INTERVENTIONS

- Examination of the TM with pneumatic otoscopy, paying careful attention to patient positioning, comfort, and speculum size to

optimize visualization and seal.
- Careful follow-up for patients when the "watchful waiting" strategy is adopted.
- Otitis media is rare in patients less than 6 months old. Pay careful attention to alternative sources of infection such as meningitis in neonates and young infants.
- CT scanning of the temporal bone and mastoid air cells in cases of suspected mastoiditis.

Common Pitfalls

- Failure to diagnose concurrent AOM.
- Failure to use a wick in severe cases.
- Failure to recognize complicating conditions (periauricular cellulitis and necrotizing OE; immunocompromised status) that require systemic antibiotics.

CHAPTER 257
Sinusitis

Kelli A. Petronis

Acute sinusitis is defined as inflammation of the mucosal lining of the nasal passage and paranasal sinuses lasting less than 4 weeks. Predisposing factors include allergens, environmental irritants, and infection. The most frequent cause of sinusitis is an upper respiratory infection (URI) (1). It is estimated that children between the ages of 6 and 35 months of age have six episodes of URI per year, and acute bacterial sinusitis (ABS) complicates viral URI in 8% (2). Children in day care have a higher risk of developing sinusitis than those in home care (3). The second most common predisposing factor in the development of childhood acute sinusitis is allergic inflammation (4). Other predisposing conditions include cystic fibrosis, immune disorders, abnormal ciliary function, nasal polyps, nasal foreign bodies (including indwelling nasal tubes), cleft palate, adenoidal hypertrophy, septal deviation, and gastroesophageal reflux disease (5).

Streptococcus pneumoniae, Haemophilus influenzae, and *Moraxella catarrhalis* are the most common etiologic agents in ABS. Visit rates for acute sinusitis in children have not decreased after the introduction of the pneumococcal vaccine (6). Although some recent studies have suggested that *Staphylococcus aureus* is a major pathogen in ABS, they should be interpreted with caution. The majority of isolates in the pediatric studies were taken from cultures of the middle meatus, which has not been established as a reliable surrogate for maxillary sinus aspirates in children (7).

CLINICAL PRESENTATION

Children with ABS present with upper respiratory symptoms that are either persistent or severe. Most viral URIs last approximately 5 to 7 days, and almost all are resolved or improving by 10 days (2). Children who have symptoms beyond 10 days without improvement should be considered to have ABS. The most common symptoms include cough and nasal discharge. The cough may be either “wet” or “dry” and is usually present in the daytime but may worsen at night. Fever or history of fever is present in about half of patients (5). The nasal discharge may be of any quality, ranging from clear to purulent, thin to thick. Malodorous breath is commonly reported by parents of preschool-aged children (8). Headache and facial pain or swelling, common symptoms of sinusitis in adults, are uncommon in children younger than 5 years of age but may be present in older children and adolescents (9).

Children who present with severe upper respiratory symptoms and high fever should also be suspected of having ABS. In the usual course of a viral URI, fever may be present during the first 48 hours but usually disappears, and purulent nasal discharge does not usually develop until later in the illness. In contrast, children with the severe onset of ABS are ill appearing and present with concurrent high fever ($>39^{\circ}C/102^{\circ}F$) and purulent nasal discharge for 3 to 4 consecutive days. In addition, they may complain of intense headache above or behind the eye or present with periorbital swelling (8).

In children, the most common manifestations of bacterial sinusitis are cough (80%), nasal discharge (76%), and fever (63%). Some children also have malodorous breath. Symptoms of headache, facial pain, and swelling are uncommon (1).

Any of the following clinical presentations are recommended for identifying patients with ABS (1):

- Persistent symptoms
  - Nasal congestion/discharge and/or daytime cough (may be worse at night) (4)
  - Lasts ≤ 10 days without any evidence of clinical improvement (1)

- Presence of fever, headache, or facial pain is variable (1)
- Severe symptoms (1,4)
  - High fever (≤39°C/102°F)
  - AND purulent nasal discharge or facial pain
  - AND lasting at least 3 to 4 consecutive days at the BEGINNING of illness
- Worsening symptoms (1)
  - New onset of fever, headache, or increase in nasal discharge following typical viral URI that lasted 5 to 6 days and was initially improving
  - If nuchal rigidity is present, the patient should be evaluated for meningitis.

Complications of acute sinusitis include bony, orbital, and central nervous system extension (10). Osteomyelitis of the frontal bone is called Pott's puffy tumor. Orbital complications include subperiosteal abscess, orbital cellulitis, and orbital abscess. Central nervous system complications include cavernous or sinus venous thrombosis, meningitis, subdural empyema, and subdural, epidural, or brain abscesses.

DIFFERENTIAL DIAGNOSIS

- Viral URI (1,4)
  - If fever is present, it typically occurs in the first 24 to 48 hours and then resolves
  - Purulent nasal discharge is not generally present until the fourth or fifth day of illness
- Sequential viral URI
- Allergic rhinitis
- Nasal foreign body (often presents with unilateral nasal discharge)

ED EVALUATION

There are no physical examination findings that are specific for sinusitis. There may be mild erythema and edema of the nasal turbinates with mucopurulent discharge, but patients with

uncomplicated viral URIs may have similar findings. Facial tenderness is rare, although reproducible unilateral pain to percussion or direct pressure over the frontal or maxillary sinus may indicate sinusitis. In addition, periorbital swelling suggests ethmoid sinusitis (2), although one must be careful to rule out true orbital complications in these patients. Findings that suggest an orbital or intracranial complication include proptosis, abnormal extraocular movements, focal neurologic deficits, or signs of intracranial pressure. If nuchal rigidity is present, the patient should be evaluated for meningitis. Transillumination is unreliable in children younger than 10 years (2).

The most important part of the emergency department (ED) evaluation is the history, since the diagnosis is usually made clinically. The physical examination is most important for ruling out complications, rather than diagnosing sinusitis. No physical examination findings are specific for sinusitis; mild erythema and edema of the nasal turbinates with mucopurulent discharge may be present, but also occur with URI (4).

Facial tenderness is rare, but reproducible unilateral pain to percussion or direct pressure over maxillary or frontal sinus may indicate sinusitis (4). Periorbital swelling suggests ethmoid sinusitis, although one must be careful to rule out true orbital complications in patients with this finding (4).

Findings suggestive of orbital or intracranial complications (5) include proptosis, abnormal extraocular movements, focal neurologic deficits, signs of increased intracranial pressure, altered mental status, or nuchal rigidity.

Sinus aspiration is the gold standard for the diagnosis of bacterial sinusitis but should only be performed by specialists. Sinus aspiration is not recommended for the routine diagnosis of ABS in children (2). Cultures of the throat and nasopharynx have poor correlation with those of maxillary sinus aspirates and are not recommended (11).

Laboratory Studies

Sinus aspiration (4) is the gold standard, but should only be performed by specialists and is not recommended for routine diagnosis of ABS in children. *Nasal/nasopharyngeal cultures* are not useful in predicting the results of culture of the paranasal sinuses themselves (8).

Imaging

Plain films are not recommended for the diagnosis of acute uncomplicated bacterial sinusitis in children by the American Academy of Pediatrics, the American College of Radiology, and the Sinus and Allergy Health Partnership. It should be reserved for children who do not improve or worsen with therapy (4).

Computed tomography (CT) scanning is recommended for patients with suspected suppurative complications such as orbital or intracranial extension (1,12). It is also indicated in patients who do not respond to therapy (12).

Magnetic resonance imaging (MRI) should be considered in those with suspected intracranial complications (13). Obstacles include limited availability, length of test, and need sedation often required in children.

There are limited studies of *ultrasound,* but there may be a role in evaluating fluid collections in the maxillary sinus in pediatric patients (12).

Findings on plain film that may help confirm a diagnosis of sinusitis include air–fluid levels, complete sinus opacification, and mucosal thickening (≤ 4 mm). Studies have shown strong correlation (80% to 92.5%) between persistent symptoms and abnormal radiographs (10,12). In studies in which sinus aspirates were taken from children with persistent or severe symptoms and abnormal radiographs, bacteria were recovered in 70% to 75% of cases (2). Because there is such a high correlation among persistent symptoms, abnormal radiographs, and positive sinus aspirates, the American Academy of Pediatrics, the American College of Radiology, and the Sinus and Allergy Health Partnership do not recommend the routine use of radiography in the diagnosis of acute

uncomplicated sinusitis in children (2). Instead, radiography should be reserved for children who do not improve with therapy or who worsen during therapy.

CT scans are indicated for patients with suspected complications, with persistent or recurrent infections, who fail to respond to therapy, and who are being considered for surgical treatment (2). MRI is also recommended for patients with suspected intracranial complications, but MRI often has limited availability.

KEY TESTING

- History and physical examination are the most important elements of the evaluation.
- CT scan is reserved for selected patients who are at risk for infectious complications, including abscess or orbital cellulitis.

ED MANAGEMENT

The most current recommendations for the management of ABS in both adults and children were published in 2012 by the Infectious Disease Society of America (IDSA) using a multidisciplinary panel. Recent randomized controlled trials of antimicrobial therapy versus placebo for treatment of ABS show a modest benefit favoring the use of antimicrobials. Therefore, the IDSA guidelines do recommend antimicrobial therapy be initiated as soon as the clinical diagnosis of ABS is made (1).

Antibiotics are the mainstay of treatment for ABS (Table 257.1). Many children will improve spontaneously without the use of antibiotics, but improvement is more rapid when antibiotics are used. In a study comparing antimicrobial treatment to placebo, 83% of children receiving antimicrobials were cured or improved by day 3, in comparison to only 51% of those in the placebo group (12). The antibiotic chosen should have adequate coverage for the most common causative organisms of ABS (see introduction). Resistance of *S. pneumoniae* to penicillins has been increasing, and attention should be paid not only to local resistance patterns but also to factors that increase the risk that a child harbors a resistant strain.

These factors include day care attendance, age younger than 2 years, and antibiotic use within 90 days (2).

TABLE 257.1
Antibiotic Recommendations

- First-line: standard dose amoxicillin–clavulanate (45 mg/kg/d orally divided twice daily) for 10–14 d
- Second-line: high dose amoxicillin–clavulanate (90 mg/kg/d orally divided twice daily) for 10–14 d reserved for the following instances outlined below.
  - Geographic areas with high endemic rates (≥10%) of invasive penicillin nonsusceptible *S. pneumoniae*
  - Severe infection (T ≥39°C/102°F)
  - Risk factors for resistance: daycare, age >2 yrs, hospitalization within past 5 d, antibiotic use within last month, comorbidities, immunocompromise
  - Failed initial therapy (symptoms worsen after 48–72 hrs or no improvement after 3–5 d)
- Alternative second-line options:
  - Clindamycin (30–40 mg/kg/d orally divided three times daily) PLUS cefixime (8 mg/kg/day orally divided twice daily) or cefpodoxime (10 mg/kg/d orally divided twice daily)
  - Levofloxacin (10–20 mg/kg/d orally every 12–24 hrs)
- Vomiting not tolerating oral antibiotics: ceftriaxone (50 mg/kg intravenously or intramuscularly) as a single dose, followed by oral antibiotic 24 hrs later if vomiting resolved
- Penicillin-allergic:
  - Type I hypersensitivity: levofloxacin (10–20 mg/kg/d orally every 12–24 hrs)
  - Non-type I hypersensitivity: clindamycin PLUS cefixime or cefpodoxime (see dosing above)
- Severe infection requiring hospitalization:
  - Ampicillin/sulbactam (200–400 mg/kg/d intravenously divided every 6 hrs)
  - Ceftriaxone (50 mg/kg/d intravenously divided every 12 hrs)
  - Cefotaxime (100–200 mg/kg/d intravenously divided every 6 hrs)
  - Levofloxacin (10–20 mg/kg/d intravenously divided every 12–24 hrs)
- *Not recommended*
  - Amoxicillin, macrolides, TMP/SMX (due to increasing resistance)
  - Second- and third-generation oral cephalosporins as monotherapy
  - Coverage for *S. aureus* (including MRSA) during initial empiric therapy

Antihistamines, decongestants, sinus irrigation (9)

From Chow AW, Benninger MS, Brook I, et al. IDSA Clinical Practice Guideline for Acute Bacterial Rhinosinutis in Children and Adults. *Clin Infect Dis*. 2012;54:e72–e112.

Amoxicillin in a usual dose (45 mg/kg/d divided bid) or high dose (90 mg/kg/d divided bid) can be used as first-line therapy in children who have mild to moderate uncomplicated ABS, do not attend day care, and have not been on antibiotics in the past 90 days. Although amoxicillin does not adequately cover β-lactamase producing organisms, approximately 80% of children without risk factors for resistance can be expected to respond to amoxicillin. This is because *S. pneumoniae* is the most common causative organism, and 50% to 75% of sinusitis caused by *H. influenzae* and *M. catarrhalis* will resolve spontaneously. In children who attend day care, have received antibiotics in the past 90 days, have moderate to severe illness, or do not improve on usual dose amoxicillin, therapy should be initiated with high-dose amoxicillin–clavulanate (80 to 90 mg/kg/d of amoxicillin component in two divided doses). In children who are allergic to penicillin, there are the following options: cefdinir (14 mg/kg/d in one or two doses), cefuroxime (30 mg/kg/d divided bid), or cefpodoxime (10 mg/kg/d once daily). In children who have had anaphylactic reactions to penicillins, many prefer instead to use clarithromycin (15 mg/kg/d divided bid) or azithromycin (10 mg/kg/d on day 1 and 5 mg/kg/d $\times$ 4 more days, given once daily). A final option in the allergic patient is clindamycin (30 to 40 mg/kg/d in three divided doses). A single dose of intramuscular (IM) or intravenous (IV) ceftriaxone (50 mg/kg) may be used for children who are vomiting, followed by completion of a treatment course with an oral antibiotic starting 24 hours later. Recent studies have shown significant resistance of *S. pneumoniae* to trimethoprim–sulfamethoxazole and erythromycin–sulfisoxazole; therefore, these antibiotics should not be used (2).

Current recommendations for length of treatment vary from 10 to 28 days. In most cases, treatment for 7 days beyond the time when the patient becomes symptom-free results in adequate treatment (2,8). Most patients become symptom-free by 3 days of treatment, so 10 days of treatment usually suffices. A good recommendation for ED treatment is treat for 10 days and have patients with longer symptomatic periods follow-up with their primary care physician for continuation of antibiotics.

Saline nasal irrigation, antihistamines, topical or systemic decongestants, mucolytic agents, and topical intranasal steroids have all been suggested as ancillary treatments, but few data exist on their efficacy, especially in children (2). In one study, intranasal budesonide spray was added to antibiotics, and a significant improvement in symptoms of cough and nasal discharge was noted in the treatment group compared to the placebo group, but only at the end of the second week of treatment (3). Another study compared the addition of topical decongestant and oral decongestant–antihistamine to placebo (in addition to amoxicillin in both groups) and found similar treatment response in both groups (6).

Any child suspected of having an orbital or central nervous system complication should be treated aggressively. This includes imaging, IV antibiotics, and emergent consultation with appropriate subspecialists. Antibiotic treatment for orbital complications should be with either ceftriaxone (100 mg/kg/d IV divided bid) or ampicillin–sulbactam (200 mg/kg/d IV in four divided doses) or an antibiotic with equivalent antimicrobial spectrum. Antibiotic treatment for intracranial complications should be with ceftriaxone (see previous dose) or cefotaxime (200 mg/kg/d divided q6h). Vancomycin (60 mg/kg/d in four divided doses) should be added if *S. pneumoniae* resistance is suspected (2).

CRITICAL INTERVENTIONS

- The diagnosis of sinusitis in children can be made based on clinical criteria: persistent upper respiratory symptoms without improvement (>10 days), severe upper respiratory symptoms (high fever AND purulent nasal discharge for 3 to 4 days), or worsening symptoms (new onset of fever, headache, or increased nasal discharge following URI that lasted 5 to 6 days and was initially improving).
- Careful examination to rule out potential orbital and central nervous system complications.

- Imaging should be reserved for toxic-appearing patients, those suspected of having complications, or those who have failed treatment.
- Antibiotic therapy should be initiated with amoxicillin–clavulanate (standard-dose or high-dose depending on risk factors) for 10 to 14 days. Options for penicillin-allergic children include levofloxacin for type I hypersensitivity reactions, and clindamycin PLUS cefixime or cefpodoxime for non-type I hypersensitivity reactions.
- Patients suspected of having orbital or central nervous system complications need aggressive treatment, including IV antibiotics, imaging, emergent consultation with the appropriate subspecialist, and hospital admission.

DISPOSITION

Uncomplicated ABS:

- Discharge from ED with appropriate antimicrobial treatment
- Follow-up with primary care physician if worsening, or if no improvement after 3 to 5 days
- Follow-up immediately if any signs or symptoms of a complication develop

Toxic-appearing, immunocompromised, or suspected orbital or intracranial complications:

- Admit
- Appropriate antimicrobials (typically parenteral)
- Appropriate imaging (typically CT)
- Subspecialty consultation (consider ENT, Ophthalmology, Neurosurgery)

Common Pitfalls

- Not performing a thorough neurologic examination and missing signs of an associated intracranial or suppurative complication of sinusitis.
- Relying on laboratories and/or imaging to make the diagnosis of sinusitis in children.

• Prescribing inappropriate antibiotics.

CHAPTER 258 Lymphadenitis

Keri L. Carstairs

Lymph nodes are commonly palpated in children's necks. Cervical nodes >10 mm are considered abnormal and referred to as lymphadenopathy (1). Enlarged lymph nodes can arise in association with a wide variety of infectious, inflammatory, or neoplastic disease processes (2). The most common cause of a benign neck mass in children is cervical lymphadenopathy secondary to an upper respiratory tract infection, usually of viral origin.

Lymphadenitis is one type of lymphadenopathy and can be either acute or chronic. Although some define lymphadenitis broadly as an "inflammation of a lymph node," others restrict the definition to include only bacterial infections (1,3).

After invading regional tissues, microorganisms enter the lymphatic system, where they are trapped and destroyed by phagocytes. This activity, coupled with the lymphocytic proliferation and transformation results in swelling of the node. Infectious organisms able to survive intracellularly can represent a persistent stimulus leading to a chronic lymphatic cell hyperplasia. Lymph nodes may become infiltrated with neutrophils in response to bacteria, with histiocytes in histiocytosis (and certain storage diseases), and with malignant cells in leukemia, lymphoma, or metastatic solid tumors (2).

In the case of bacterial infection, abscess formation may ensue when neutrophils accumulate within lymph nodes. (1,4). Group A β-*hemolytic Streptococci* sp and *Staphylococcus aureus* are the most frequent pathogens of bacterial lymphadenitis, accounting for nearly 95% of acute bacterial lymphadenitis. Children with staphylococcal

infections generally have a longer history of symptoms and an increased incidence of fluctuance compared with those with streptococcal infections (1,4,5).

CLINICAL PRESENTATION

Cervical lymphadenitis presents most commonly in children between 1 and 4 years of age, and there is no significant difference in incidence between genders. It is helpful to determine whether the cervical lymphadenitis developed in an acute, subacute, or chronic manner. The acute bacterial nodal enlargement usually develops rather quickly and unilaterally. These nodes are typically very tender and sometimes feel fluctuant. Erythema of the overlying skin is occasionally noted. Affected children often experience malaise and irritability and may be febrile. Frequently, a concurrent pharyngitis, otitis media, upper respiratory tract infection, dental abscess, or adjacent skin infection can be detected, or a recent history of infection can be elicited. Subacute or chronic lymphadenitis develops in 2 to 3 weeks and tends to be relatively painless. Lymphadenitis may be caused by catscratch disease, atypical mycobacteria, or tuberculosis.

Acute bilateral lymphadenitis most often occurs in response to an acute upper respiratory infection such as pharyngitis caused by viral pathogens or *Streptococcus pyogenes* and *Mycoplasma pneumoniae.* These nodes are usually small, soft, can be either tender or nontender, and do not have associated erythema or warmth.

There are rarely significant sequelae when adenitis is managed appropriately. Of particular concern is the possibility of misdiagnosing and consequently mismanaging another more serious problem (6). It is sometimes difficult to distinguish lymphadenopathy or adenitis from a true neck mass. Neck masses may be congenital or acquired, infectious or neoplastic, benign or malignant. In children, the incidence of neoplastic lesions is low compared to adults. In neither group does the neck mass commonly present as an acutely emergent or life-threatening problem.

DIFFERENTIAL DIAGNOSIS

Obtaining a careful history and performing a complete examination can often differentiate the disorders most commonly confused with adenitis (Table 258.1) (6).

TABLE 258.1
Differential Diagnosis of Lymphadenitis

Differential Diagnoses	Causative Agents	Comments
		Viral
Lymphadenopathy	Adenovirus	Lymphadenopathy usually resolves within a few days to 2 wks
	EBV	Often bilateral
	CMV	Respiratory viruses commonly involved
	Human herpesvirus 6	
	Coxsackie	
	Rubella	
	Rubeola	
	Varicella (5,7)	
Bacterial lymphadenitis	Group A *β-hemolytic streptococcus*	Erythema, warmth, and tenderness overlying a node typically indicates bacterial lymphadenitis
	Staphylococcus aureus	Rubbery or firm in consistency and freely mobile
		Often unilateral
		Untreated nodes tend to suppurate and may rupture onto the skin or dissect into underlying soft tissues
Infectious mononucleosis	EBV	Often presents as acute or subacute cervical lymphadenopathy
		Nodes tend to be posterior cervical, bilateral, and moderately painful
		Associated findings include malaise, fever, tonsillopharyngitis, hepatosplenomegaly, and generalized node enlargement
		Positive heterophil (Monospot) confirms the diagnosis except in children younger than 4 yrs for whom EBV titers should be done
		Treatment is supportive; avoid contact sports for several months
Catscratch disease	*Bartonella henselae*	In approximately 50% of cases, primary lesion is at the site of a 7–14-d-old scratch or bite by a cat
		Begins as indurated erythematous papule and later may become vesicular or pustular; resolves in 10–20 d
		Days to weeks later, the nodes draining this area become enlarged
		Nodes are typically only moderately tender but occasionally suppurate
		Associated symptoms include fever, headache, myalgia or malaise
		Complications such as encephalitis, hepatosplenic abscess, and osteolytic lesions are uncommon
		Consider azithromycin to shorten the clinical course
Atypical mycobacterial lymph-adenitis	Nontuberculous mycobacteria	Subacute or chronic unilaterally enlarged lymph nodes.
		Does not respond to antibiotics
		Infected nodes tend to be relatively painless
		Systemic symptomatology is uncommon
		Tuberculin skin testing is unreliable
		Treatment of choice is excisional biopsy
Kawasaki disease	Unknown	Also known as mucocutaneous lymph node syndrome
		Diagnosed in the presence of fever plus four of the diagnostic criteria including cervical lymphadenopathy, rash, oral exanthem, conjunctival injection, and swelling and redness of palms and soles
		Exclusion of other illnesses is necessary
		Cervical lymphadenopathy is only found in 50% of cases
		Nodes are usually unilateral and confined to the anterior triangle
		Early diagnosis is critical because treatment can prevent coronary aneurysm
Tuberculous lymphadenitis	*Mycobacterium tuberculosis*	Rare
		Diseased nodes are similar to those of nontuberculous mycobacterial adenitis
		Workup includes history of TB exposure, a TB skin test, and chest x-ray
		Tuberculous lymph nodes should never be aspirated because this could lead to sinus development
		Antituberculous drugs are effective in treating this condition
		Infection should be reported to public health authorities
Group B streptococcal cellulitis–adenitis syndrome	Group B *Streptococcus* sp	This syndrome occurs in neonates;
		Abrupt onset of fever and facial or submandibular erythema and swelling
		Symptoms include irritability, poor feeding, and toxicity
		About 80% have ipsilateral otitis media
		Meningitis may accompany lymphadenitis
		Organism can be isolated from blood and lymph node or cellulitis aspirates
		Complete sepsis workup should be performed, admission and IV antibiotics
Toxoplasmosis	*Toxoplasma gondii*	May present as single, enlarged, posterior cervical node that may or may not be tender
		Nodes vary in size but do not suppurate
		The diagnosis can be made by performing serial toxoplasma titers
		Pharmacologic therapy should be withheld unless fever or a complication such as pneumonitis, myocarditis, meningitis, or encephalitis ensues

EBV, Epstein–Barr Virus; CMV, cytomegalovirus; TB, tuberculosis.

Viral Lymphadenopathy

Viral infections, especially those producing viremia, are the most common cause of lymphadenopathy in children and usually subside within a few days to 2 weeks. Often bilateral, causative agents include respiratory viruses such as herpes simplex gingivostomatitis, adenoviral syndromes, roseola, Enterovirus, human herpesvirus 6, Coxsackievirus, rubella, rubeola, varicella and infectious mononucleosis caused by Epstein–Barr virus (EBV), or cytomegalovirus (CMV) (1,2,4).

Bacterial Lymphadenitis

The presence of erythema, warmth, and tenderness overlying a node typically indicates the acute inflammatory response of pyogenic bacterial lymphadenitis. Most acutely infected nodes in children are rubbery or firm in consistency and are freely mobile. Left untreated, these nodes, often unilateral, tend to suppurate and may rupture onto the skin or, less commonly, dissect into the underlying soft tissues (1,4,5).

Infectious Mononucleosis

EBV causes infectious mononucleosis. It often presents as acute or subacute cervical lymphadenopathy. These nodes tend to be posterior cervical, bilateral, and moderately painful (4). They are present in 93% of infected children (2). Associated findings include malaise, fever, tonsillopharyngitis, hepatosplenomegaly, and generalized lymph node enlargement. A positive heterophil test (Monospot) confirms the diagnosis. In children younger than 4 years of age, the heterophil test is unreliable, and specific EBV titers should be done. Treatment is supportive. The patient should be instructed to avoid contact sports for several months after the illness because of the risk of splenic rupture. Rarely, cervical lymphadenopathy in infectious mononucleosis is associated with respiratory distress because of extremely enlarged (“kissing”) tonsils, and this condition may require hospitalization and steroid use.

Catscratch Disease

Most cases of catscratch disease are caused by *Bartonella henselae.* In approximately 50% of cases, there is a primary lesion at the site of a 7- to 14-day-old scratch or bite by a cat. This lesion begins as an indurated erythematous papule and later may become vesicular or pustular. The lesion resolves within 10 to 20 days. Catscratch disease usually presents subacutely. Several days to weeks later, the lymph nodes draining this area become progressively enlarged. The most common sites of lymphadenopathy are the axilla (52%) followed by the neck (28%) (2). These nodes are typically only moderately tender, but occasionally will suppurate. Sometimes, patients are febrile and may experience headache, myalgia, or malaise. Other complications, such as encephalitis, hepatosplenic abscesses, and osteolytic lesions, are uncommon. Although the diagnosis is usually made on clinical grounds, it can be confirmed serologically. The adenopathy generally resolves in 6 to 8 weeks with supportive treatment only. However, azithromycin is recommended for lymphadenopathy related to catscratch disease (5). Fluctuant nodes often need surgical intervention (1,8–10).

Methicillin-Resistant *Staphylococcus aureus*

With the changing epidemiology of methicillin-resistant *Staphylococcus aureus* (MRSA) infection in healthy individuals, this bacterium should be considered when patients present with soft tissue infections. MRSA should be considered in patients presenting with cervical lymph node swelling (11). MRSA infections can also occur in healthy newborns (11,12).

Mycobacterial Lymphadenitis

Atypical mycobacterial cervical lymphadenitis usually presents as subacute or chronic unilaterally enlarged lymph nodes that do not respond to antibiotics (1,13). Nontuberculous mycobacterial lymphadenitis generally occurs in early childhood. Infected nodes tend to be relatively painless but are sometimes tender and may even suppurate and drain. Systemic symptomatology is uncommon. Tuberculin skin testing is unreliable. Antituberculous drugs are not

recommended, and excisional biopsy is both diagnostic and therapeutic (14).

Tuberculous lymphadenitis is rarely seen in the United States (10,15,16). Diseased nodes are similar to those of nontuberculous mycobacterial adenitis. To exclude the diagnosis, the family should be questioned about their exposure to tuberculosis, a tuberculin skin test should be done, and a chest radiograph ordered. Tuberculous lymph nodes should never be aspirated, because aspiration may lead to sinus development. Antituberculous drugs are effective in treating this condition. Lastly, infection should be reported to public health authorities.

Kawasaki Disease

Also known as mucocutaneous lymph node syndrome, Kawasaki disease is diagnosed in the presence of fever, plus four of the five diagnostic criteria (cervical lymphadenopathy, rash, oral exanthem, conjunctival injection, and swelling and redness of palms and soles) and exclusion of other illnesses. Cervical lymphadenopathy is found in only 50% of cases. Nodes are usually unilateral and confined to the anterior triangle, moderately tender, nonfluctuant, and firm, with or without overlying erythema. The early diagnosis of Kawasaki disease is critical, because treatment with salicylates and intravenous immunoglobulin can prevent serious complications, namely, coronary aneurysm (10).

Group B Streptococcal Cellulitis–Adenitis Syndrome

The group B streptococcal cellulitis adenitis syndrome occurs in neonates (5). The neonate presents with the abrupt onset of fever, facial or submandibular erythema and swelling, irritability, poor feeding, and toxicity. About 80% have an ipsilateral otitis media. Meningitis may accompany lymphadenitis. The organism can be isolated from blood and from aspirates of the lymph node or the cellulitis. A complete sepsis workup should be performed, and the infant must be admitted to the hospital for intravenous antibiotic therapy (5,10,17).

Toxoplasmosis

Acquired toxoplasmosis sometimes presents as a single, enlarged, posterior cervical node that may or may not be tender (1,18,19). These nodes tend to vary in size but do not suppurate. The diagnosis can be made by performing serial toxoplasma titers. Pharmacologic therapy should be withheld unless fever or a complication such as pneumonitis, myocarditis, meningitis, or encephalitis ensues.

Other Infectious Etiologies

Other uncommon causes of cervical lymphadenopathy include *Pasteurella multocida, Yersinia pestis,* histoplasmosis, and CMV.

Rheumatologic Lymphadenopathy

A number of rheumatologic illnesses can cause cervical lymphadenopathy; chief among them is juvenile rheumatoid arthritis.

Neoplasms

Neoplasms are rare in children, occurring in 1.4% of patients younger than 17 years of age with a superficial lump on any part of the body. Careful follow-up of all lymphadenopathy is mandatory, especially if it is associated with fever or weight loss or if it fails to resolve (1,9,20).

Benign neoplasms in children that present as neck masses include hemangiomas, lymphangiomas, fibromas, neurofibromas, and lipomas. Malignant neck neoplasms in children tend to be single, nontender, *immobile,* and *fast growing* and are located in the posterior triangle of the neck. Age is a key element in the occurrence of the various malignant neck neoplasms. From ages 1 to 5, neuroblastoma, rhabdomyosarcoma, histiocytic lymphoma, and Hodgkin disease are the most common. In the older child, histiocytic lymphoma and Hodgkin disease occur equally often. The adolescent most commonly acquires Hodgkin disease. Rhabdomyosarcoma is the most common pediatric solid tumor of the head and neck and one of the most

common tumors in children younger than age 6; frequently presenting with rapid growth in the orbit, nasopharynx, ear, mastoid, face, or tongue. Neuroblastoma is the most common solid tumor in children overall, but presents as a neck mass only about 5% of the time.

ED EVALUATION AND MANAGEMENT

Many of the aforementioned diagnoses can be made simply by taking a complete history and performing a thorough examination. The following points should be addressed when questioning the family: duration of adenopathy or mass; history of an adjacent skin lesion, earache, upper respiratory tract infection, sore throat, or dental problem; presence of fever or weight loss; exposure to tuberculosis; contact with cats; and travel (1,4). When attempting to determine whether a neck mass may be a lymph node, it is important to recognize the location of the normal chain of cervical lymph nodes. The size, consistency, mobility, and tenderness of each affected node must be noted (1,10). Marking the dimensions with ink and recording them in the emergency department (ED) record can be helpful to the next physician who evaluates the patient. The head, ears, eyes, nose, oropharynx, and neck are examined, and the child is evaluated for hepatomegaly, splenomegaly, and other adenopathy (1).

Useful studies include a complete blood cell count, erythrocyte sedimentation rate, C reactive protein, a Monospot or EBV serology, a throat culture for group A *Streptococcus* sp, and a tuberculin skin test. It is unnecessary to order all of these tests on every patient. The tests prove most helpful when the cause of the adenopathy is unknown. A blood culture should be obtained if the patient appears toxic. Older children with cervical adenitis are rarely bacteremic, but neonates often are and must be evaluated for possible sepsis (17). Additional studies may be needed in the older child, depending on the history and physical examination (e.g., serology for catscratch disease or EBV). Sometimes, a definitive diagnosis is not made until a biopsy is performed.

Needle aspiration is useful both diagnostically and therapeutically, and any fluctuant node should be aspirated if tuberculous lymphadenitis cannot be excluded. An ultrasound can help determine whether a node or mass is cystic or solid, if necessary (22). The largest, most fluctuant node is selected, the overlying skin is cleansed, a 20-gauge needle attached to a 20-mL syringe is inserted into the fluctuant region, and aspiration is done. If pus is not obtained, 1 to 2 mL of sterile, nonbacteriostatic saline is injected into the node, which is reaspirated. The aspirate is sent for Gram stain and cultures for aerobic bacteria, anaerobic bacteria, mycobacteria, and fungi (1,2,4).

If bacterial cervical lymphadenitis is suspected, treatment with antibiotics effective against the principal bacterial pathogens, group A β-*hemolytic Streptococcus* sp and *S. aureus,* should be initiated. Analgesics and warm compresses may also be helpful (1). Most patients can be successfully managed as outpatients with follow-up arranged. Outpatient and inpatient therapy is outlined in Table 258.2 (1,18,23). Failure to respond to oral antibiotics does not necessarily mean the cause of adenitis is not bacterial; parenteral antibiotics may be required. If the lymphadenitis is associated with dental disease, anaerobic infection needs to be considered (1,23).

TABLE 258.2
Management of Bacterial Lymphadenitis

Outpatient Therapy (3,6,13)	Inpatient Therapy (3,6,13)
1. Cefadroxil 30 mg/kg/d divided q12h PO	1. Cefazolin 100 mg/kg/d divided q8h IV
2. Clindamycin 20 mg/kg/d divided q8h PO	2. Clindamycin 40 mg/kg/day divided q6h to q8 h IV
3. Cefuroxime 20 mg/kg/d divided q12h PO	3. Nafcillin 125 mg/kg/d divided q6h IV
Failure to respond to oral antibiotics does not necessarily mean that the cause of adenitis is not bacterial; parenteral antibiotics may be required	
If the lymphadenitis is associated with dental disease, anaerobic infection needs to be considered, and the following agent is recommended: amoxicillin–clavulanate (Augmentin) 45 mg/kg/d divided q12h PO (3,5)	
Treatment should last at least 10 d (5,12). After a good response to parenteral antibiotics is observed, oral agents can be substituted (5)	

PO, by mouth; IV, intravenous.

KEY TESTING

- History and physical examination should drive testing and treatment decisions
- Neonates and children who are septic-appearing should have CBC, CRP, ESR, and blood cultures obtained
- Ultrasound can be used to differentiate solid from cystic masses
- Aspiration of fluid for Gram stain and culture when indicated by history and physical examination.

CRITICAL INTERVENTIONS

- Take a detailed history, including travel and animal contact, to differentiate lymphadenitis from other disorders.
- Arrange follow-up for all case of lymphadenitis, especially for patients with large nodes, fever, weight loss, or other concerning systemic signs.

DISPOSITION

Most children can be managed successfully as outpatients. They should be reevaluated, to monitor their progress, within 2 to 3 days of the ED visit. Follow-up is very important and is done best by the patient's primary care physician, who should reexamine the child serially until the node regresses.

Admission for intravenous antibiotics is warranted if the child appears toxic, if the lymphadenitis is severe (e.g., node diameter >3 to 4 cm or high fever), if the lymphadenitis fails to respond to oral medications, or if the patient is a neonate or cannot tolerate oral antibiotics (18). Admission for further evaluation is recommended if there is mediastinal lymphadenopathy on the chest radiograph, weight loss, fever for more than 1 week, or a suspicion of Kawasaki disease or malignancy (9).

Biopsy is indicated if the node increases in size or does not decrease in 4 to 6 weeks or return to normal in 8 to 12 weeks (9). Particularly worrisome findings are weight loss, persistent fever, or fixation to adjacent tissues or overlying skin (1,4,7).

Common Pitfalls

- Treating patients with severe lymphadenitis orally and delaying an inevitable admission for intravenous antibiotics.
- Failure to consider atypical mycobacterial lymphadenitis, Kawasaki disease, and catscratch disease in the differential diagnosis.

CHAPTER 259 Torticollis

Robert L. Cloutier

Torticollis is derived from the Latin words *tortus,* meaning "twisted," and *collum,* meaning "neck." Medically, it is defined as "a contraction, often spasmodic, of the muscles of the neck; the head is drawn to one side and usually rotated so that the chin points to the other side." It is a manifestation of illness, not a disease itself, which means that one needs to determine the etiology. Depending on the etiology and time of onset, torticollis is classified as either congenital or acquired.

CLINICAL PRESENTATION

In the newborn, torticollis often presents as a firm, nontender, unilateral enlargement in the sternocleidomastoid muscle noticed shortly after birth (1). There may be associated findings such as plagiocephaly and facial asymmetry (2).

Older children present with the head rotated on the neck, tilted to the affected side, with the chin pointed to the opposite direction of the spasm. In addition, they may complain of intermittent, painful muscle spasms.

DIFFERENTIAL DIAGNOSIS

Congenital Torticollis

Congenital causes include both malformations (defect during morphogenesis) and deformations (secondary to intrauterine postures and crowding).

Malformations can occur in the cervical spine, the cervical musculature, or the central nervous system. A number of rare cervical spine anomalies can cause torticollis, including odontoid hypoplasia, cervical spine fusions (Klippel–Feil), spina bifida, hemivertebrae, and scoliosis (3,4). Torticollis can also result from deformations of the spine caused by intrauterine positioning secondary to uterine tumors, oligohydramnios, or multiple gestations. These cases are usually transient and resolve within a few months (4).

"Pseudotumor of infancy" and congenital muscular torticollis occur with an incidence of 0.4% and 1.3%, respectively (5). Intrauterine factors may cause muscle injury by an intramuscular compartment syndrome that results in localized ischemia and unilateral fibrous contracture of the sternocleidomastoid (3,6,7). There is a higher prevalence in breech births, in deliveries assisted by forceps, and in patients with cephalohematoma, clavicular fracture, or brachial plexus injury (2,3). It is typically diagnosed prior to 1 month of age and resolves by 6 months of age (6). On physical examination a firm, nontender, immobile mass is noted (1).

Congenital ocular disturbances, usually fourth nerve palsies with resultant strabismus, may be of the cause of torticollis presenting later in infancy, representing approximately 4% of cases (3,8).

Acquired Torticollis

The causes of acquired torticollis are varied. Trauma to the cervical spine from subluxation, fracture, or dislocation is among the most important causes to consider in the ED setting. The trauma can be relatively minor, as from the hyperflexion/hyperextension of a "whiplash" injury. In some cases the onset of symptoms may be delayed by several months (4). The most commonly areas affected are the atlantoaxial area and the junction of C-2 on C-3; ligamentous laxity in the atlantoaxial region can be a contributing factor in subluxation (4). These cases are often associated with underlying disorders such as trisomy 21 (Down syndrome), mucopolysaccharidosis, and invasive erosion from a surrounding

soft tissue infection (3,8). Cervical spine infections, such as osteomyelitis and discitis, and metastatic or primary osteomas can also present as torticollis (4,8).

Other causes of torticollis are not associated with cervical spine pathology. They include clavicle fracture, with splinting because of pain, nasopharyngeal or retropharyngeal abscess, cervical adenitis, tonsillitis, mastoiditis, and sinusitis (3,4,8,9). If the infection is extensive, there may be erosion of paraspinous ligaments, with rotatory subluxation in the atlantoaxial region (4). In one study, 37% of patients with computed tomography (CT)-confirmed retropharyngeal abscess had physical examination findings consistent with torticollis (10). Interestingly, pseudotumor cerebri can present as torticollis in older children (11).

Paroxysmal torticollis of infancy presents between the ages of 2 and 8 months and is due to vestibular dysfunction. It is often associated with vomiting, pallor, ataxia, or irritability and is usually self-limited, resolving by age 2 to 3 years (12–14).

Dystonic reactions to medication, most commonly phenothiazines, can present as torticollis but are usually also associated with other symptoms. The diagnosis is made by the presence of ocular symptoms (oculogyric crisis) and response to appropriate therapy.

The nuchal rigidity of bacterial meningitis can be confused with torticollis in younger patients, but torticollis will not typically be the only symptom. In rare instances torticollis can be an indication of severe underlying disease such as posterior fossa tumor, encephalomyelitis, or spinal epidural hematoma (15).

ED EVALUATION

In infants, especially those younger than 1 month of age, a careful birth history should include birth presentation and the use of forceps. Physical examination often shows a sternocleidomastoid mass, making the diagnosis of “pseudotumor of infancy.” Findings consistent with brachial plexus palsy or fractured clavicle are diagnostic of torticollis due to these etiologies.

Careful questioning is important to determine the onset, severity, location, and radiation of the pain and abnormal neck posture. In classic cases of torticollis, there is unilateral neck pain which may radiate to the ipsilateral shoulder. Historical data concerning fever and constitutional signs and symptoms help identify infectious or inflammatory causes. A careful medication history should be helpful in identifying recent phenothiazine ingestion.

In older children, acute torticollis often presents after trauma. Even with seemingly mild trauma, radiographic evaluation of the cervical spine (with plain films or CT) is often necessary to rule out fracture or subluxation. If no injury is found, a thorough examination of the head, eyes, ears, nose, and throat should be performed to search for inflammatory or infectious causes. Screening radiographs to search for underlying osseous abnormalities are not useful, given the low yield of plain films, and can lead to further unnecessary testing (16).

Physical examination findings should be able to clearly distinguish torticollis from the nuchal rigidity of meningitis. Bony pain or crepitus on palpation of the clavicle suggests fracture. Neurologic examination should reveal no motor or sensory deficit in congenital muscular torticollis or in torticollis due to muscle spasm. A finding of papilledema requires further workup (11).

The evaluation of chronic torticollis depends on whether it is episodic or constant. For episodic cases, neurologic examination and a careful history of drug and medication use are important. Torticollis that is constant requires a careful ophthalmologic examination for strabismus and neurologic examination for subtle neurologic signs (including cerebellar signs).

KEY TESTING

- Cervical spine imaging (plain film, CT, MRI) in cases of traumatic or acquired torticollis
- Funduscopic examination
- Neurologic examination

ED MANAGEMENT

Patients younger than 1 month of age who present with a physical examination consistent with "pseudotumor of infancy," brachial plexus injury, or clavicle fracture from birth injury should be referred to their pediatricians for follow-up. Similarly, those with a history and examination consistent with an intrauterine deformity due to multiple gestation, uterine tumor, or oligohydramnios should also be referred for follow-up.

Older children with a history of trauma but no radiographic abnormalities are given anti-inflammatories (ibuprofen 10 mg/kg body weight every 8 hours). Children with muscular spasm as the etiology of torticollis are managed similarly.

Those without a history of trauma are managed according to the presumed etiology. Abnormalities on neurologic examination are an indication for brain imaging with CT or MRI. Signs and symptoms of an infectious or inflammatory process should trigger appropriate diagnostic studies prior to institution of antibiotic treatment or other therapy. In torticollis related to phenothiazine use, diphenhydramine (2 mg/kg body weight IV [50 mg maximum]) will counteract the dystonic reaction.

Depending on the etiology, consultation with neurosurgery, neurology, ophthalmology, or radiology should be considered.

CRITICAL INTERVENTIONS

- Obtain neurosurgical consultation for patients with evidence of cervical spine injury or other abnormality.
- Consider phenothiazine ingestion as a cause of acute torticollis.

DISPOSITION

Follow-up by the primary care pediatrician is sufficient in infants with "pseudotumor of infancy" or congenital muscular torticollis. Most cases resolve spontaneously or with conservative physical therapy; only 10% to 20% progress and require other intervention (6,7).

Treatment for the underlying cause of the torticollis is the mainstay of management. Neurosurgical consultation should be obtained for all patients with evidence of cervical spine fracture, subluxation, or dislocation.

Common Pitfalls

- Failure to consider nonmuscular causes of torticollis.
- Failure to immobilize the neck and to rule out fracture or subluxation in patients with a history of trauma.
- Failure to consider phenothiazine side effects, even at therapeutic dosages.
- Failure to consider infectious causes (e.g., retropharyngeal abscesses or cellulitis).

CHAPTER 260 Pharyngitis

Denis Pauze

Sore throat is a common chief complaint among pediatric emergency department (ED) patients, and accounts for more than 7 million ED visits annually (1). Many infectious agents cause acute inflammation of the tonsils and pharynx, including Epstein–Barr virus (EBV), adenovirus, parainfluenza virus, rhinoviruses, group A and other β-*hemolytic streptococci,* and *Mycoplasma pneumoniae* (2–5). Nonbacterial agents are the cause of pharyngitis in 70% to 85% of patients, especially in adolescents and in children younger than 2 years of age (3).

Group A β-*hemolytic Streptococcus* (GABHS) remains the most important cause of acute pharyngitis (2–4). Though other pharyngeal infections typically resolve without intervention, GABHS infection if inadequately treated may lead to suppurative complications, including peritonsillar and retropharyngeal abscesses, sinusitis, otitis media, mastoiditis, cervical adenitis, and the nonsuppurative complication of acute rheumatic fever (ARF). Given the breadth of illnesses and potential associated complications, for individual and public health reasons, GABHS infections should be diagnosed and effectively treated.

CLINICAL PRESENTATION

Generally, patients with pharyngitis complain of a sore throat. Additional symptoms may include fever, headache, nausea, vomiting, myalgias, dysphagia, cough, runny nose, and fatigue.

GABHS pharyngitis has an incubation period of 2 to 5 days and affects children between ages of 5 and 15, mostly during the winter and spring months (3). Transmission occurs via respiratory droplets and is associated with close contact (3). Most children with acute pharyngitis present with one or more complaints in addition to sore throat. Those with GABHS infection typically report the sudden onset of throat pain which may be associated with fever, headache, abdominal pain, nausea, or vomiting (2–4). On physical examination, patients with streptococcal pharyngitis usually have tonsillopharyngeal erythema with or without tonsillar exudates, palatal petechiae, and tender anterior cervical adenopathy (2–4). Other findings may include a beefy, red, swollen uvula, excoriated nares (especially in infants), and rarely a fine, diffusely papular erythroderma ("sandpaper" or scarlatiniform rash) in cases of toxin-producing strains of GABHS (4). Bacterial pharyngitis is uncommon in children younger than 3 years; patients in the 3- to 5-year age group are more likely to present atypically with copious purulent rhinorrhea, as opposed to pharyngeal exudates (1,2).

No findings are specific for GABHS pharyngitis, and patients frequently exhibit atypical combinations of signs and symptoms compared to those considered "classic" (4). For example, some children may present with abdominal pain as the chief complaint. A systematic review evaluating the predictive accuracy of signs and symptoms in GABHS identified no single diagnostic sign or symptom. However, five findings were noted to increase diagnostic accuracy by to more than 50%: scarlatiniform rash, palatal petechiae, pharyngeal exudates, vomiting, and tender cervical lymph nodes (6).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes a number of life-threatening conditions. Pertinent negatives related to these diseases should be noted as part of the evaluation. These conditions include Kawasaki disease, Stevens–Johnson syndrome, epiglottitis, Lemmiere syndrome, deep space abscesses (both retro- and peripharyngeal

abscesses), and Ludwig's angina. Other less threatening but nonetheless important agents include EBV, herpes simplex virus, adenovirus, parainfluenza viruses, rhinovirus, and human immunodeficiency virus. Important bacterial causes besides GABHS include *Fusobacterium necrophorum, Neisseria gonorrhoeae,* group C streptococcus, Mycoplasma, and Corynebacterium.

Fortunately, epiglottitis due to *Hemophilus influenzae* type B (Hib) is now rare in the developed world thanks to widespread use of the Hib vaccine. Presently, viruses, non-B Hemophilus serotypes, and other bacteria are the primary causes of acute epiglottitis. Changing trends in the post-Hib vaccination era note a shift towards older patients, with an increase in the mean age of disease from 5.8 to 14.6 years over the decade 1992 to 2002 (7). Conversely, national trends found an increase in cases of epiglottitis in infants less than 1 year of age from 1998 to 2006 (8). While the overall incidence has decreased, however, cases of pediatric epiglottitis occur and the diagnosis should be suspected in immunosuppressed or unvaccinated or partially vaccinated children.

Lemmiere syndrome is a life-threatening form of pharyngitis caused by normal oropharyngeal bacteria (including anaerobic gram-negative bacteria such *F. necrophorum*). It is characterized by sore throat or pharyngitis, bacteremia, and thrombosis of the internal jugular vein. Although rare, Lemmiere syndrome is rising in incidence (9). Patients are usually adolescents or young adults with fever and pharyngitis who often have failed outpatient antibiotic treatment for suspected GABHS. Patients are often ill-appearing, with swelling or tenderness over the sternocleidomastoid muscle, and may have respiratory complaints related to an associated pneumonia or septic pulmonary emboli. Demonstration of a jugular vein thrombosis by CT or ultrasound can make the diagnosis early.

Acute pharyngitis may be accompanied by peritonsillar, parapharyngeal, or retropharyngeal abscess. Patients with deep tissue abscess appear ill, are febrile, and have localized pain. A patient with a peritonsillar abscess often presents with trismus, a muffled ("hot potato") voice, and unilateral swelling of the soft palate with uvular deviation away from the affected side.

Parapharyngeal abscess is frequently associated with tender unilateral neck swelling on the affected side. Younger children with acute pharyngitis may develop retropharyngeal lymphadenitis that spreads into the retropharyngeal space. The diagnosis of retropharyngeal abscess should be considered, along with epiglottitis, in a toxic-appearing toddler with dysphagia, drooling, signs of airway obstruction, and pain with neck movement.

ED EVALUATION

The diagnosis of acute pharyngitis can be made from historical and physical examination findings, but differentiating GABHS from other causative organisms is challenging. Patients with GABHS may have more significant pharyngeal inflammation, prominent exudates, and tender anterior cervical lymphadenopathy than patients with viral etiologies, but these findings are not reliable. Numerous studies over the past 60 years document clinicians' inability to clinically differentiate GABHS from non-GABHS pharyngitis (6). Certain signs or symptoms may be more suggestive of nonstreptococcal causes, however. For example, *Mycoplasma* often presents with a history of prolonged cough or pneumonia or bronchitis (2,4). EBV may present with extreme fatigue, significant pharyngeal exudates, generalized lymphadenopathy, and/or hepatosplenomegaly. Adenoviral pharyngitis is typically accompanied by nonpurulent conjunctivitis and preauricular adenopathy. Coxsackie pharyngitis is associated with the discrete painful posterior pharyngeal ulcers of herpangina, whereas parainfluenza virus causes croup or laryngitis in older children.

While no sign or symptom is specific or sensitive enough to diagnose GABHS, a number of clinical decision rules (CDRs) have been developed to aid diagnosis. The Centor criteria are perhaps the best known and consist of four signs, with one point each given for fever, exudates, tender nodes, and absence of cough. Patients with a score of 0 or 1 are presumed to have viral pharyngitis and require no further testing, whereas higher scores are progressively more likely to reflect GABHS infection. The performance of CDRs for the

diagnosis of GABHS in the pediatric population however, is weak at best (4).

In spite of these diagnostic challenges, patients with pharyngitis must be evaluated for conditions that require acute intervention; these include airway compromise, pain, and dehydration. Edematous tonsils may obstruct the upper airway, resulting in respiratory distress or sleep apnea. Often, children refuse to drink because of pain and can become dehydrated, occasionally requiring admission. Secondly, patients should be evaluated for suppurative complications. A CT scan of the neck with intravenous contrast may be indicated if a deep space abscess is suspected.

Patients should be evaluated for GABHS using a rapid antigen detection test (RADT), if available. RADTs provide quick and highly specific identification of the GABHS antigen and have been shown to increase appropriate care of ED patients with GABHS pharyngitis (10). Recent data suggest that RADTs using newer technologies such as optical immunoassay or DNA probes may be more sensitive than other RADTs and perhaps sensitive enough for use without a confirmatory backup throat culture (3,6,11). However, in contrast to diagnostic recommendations for adults with pharyngitis, numerous advisory groups continue to recommend that confirmatory cultures be performed in children and adolescents with negative RADTs because of the relatively higher pediatric incidence of streptococcal infection and ARF (6,11). These advisory groups recommend that physicians who elect to use any RADT in children and adolescents without confirmation of negative results by blood agar plate (BAP) culture should do so only after adequately demonstrating in their own practice that their RADT is as sensitive as BAP culture, which remains the gold standard for diagnosis of GABHS pharyngitis (3,6,11). False-negative RADTs often result from obtaining inadequate amounts of tonsillar or pharyngeal secretions on the specimen swab. To minimize false-negative results, specimens should be obtained by vigorous swabbing of both tonsils and the posterior pharyngeal wall (1,4,6).

ED MANAGEMENT

For airway obstruction secondary to enlarged tonsils, a nasopharyngeal airway should restore airway patency and intravenous fluid resuscitation and analgesics may be used to treat acute dehydration and pain. Most often, analgesics such as acetaminophen or ibuprofen in association with cold fluids provide adequate pain relief. Steroid treatment for pain relief still remains controversial. The Infectious Disease Society of America does not currently recommend steroid therapy for pain relief, but the topic remains controversial and there is evidence to support their use (5,12).

If GABHS is identified by laboratory testing, antibiotic therapy is currently recommended in the United States. Although antimicrobial therapy for GABHS may shorten the clinical course of illness, the disease is usually self-limited, with resolution within 3 or 4 days, even without treatment (4). This is why some countries do not treat GABHS pharyngitis. Therapy can be postponed up to 9 days from initial to the onset of symptoms and still safely prevent rheumatic fever; empiric therapy is thus not recommended (1,2,4,7). Numerous antibiotics are effective for GABHS pharyngitis (4). However, penicillin—an inexpensive drug with a narrow spectrum of activity and well-proven efficacy and safety—remains the drug of choice (1–4). A 10-day course of oral penicillin V is recommended at 400,000 U (250 mg) two to three times daily for children weighing 27 kg (60 lb) or less, or 800,000 U (500 mg) twice daily for those weighing more than 27 kg (1). In patients who are felt to be unlikely to complete a 10-day course of therapy, benzathine penicillin G, 600,000 U intramuscularly, should be given to children weighing less than 27 kg (60 lb), and 1.2 million U to larger children (1,3). Amoxicillin for 10 days at the doses described is equivalent to penicillin and may improve compliance, given its better palatability in suspension.

From a compliance perspective, 10-day treatment regimens have become controversial. It is estimated that only about 10% of patients complete a full 10-day course of antibiotics, but with no

increased incidence of complications (13). Shorter courses have been studied, including the use of azithromycin or cephalosporins (10). A recent Cochrane review included over 13,000 cases of confirmed GABHS pharyngitis and compared short-course antibiotics to standard 10-day treatment with penicillin and found them to be equivalent (14). Preliminary data suggest that a 10-day course of oral amoxicillin given as a single-daily dose is as effective as 10 days of penicillin V given three times daily (1,4). If confirmed by additional studies, once-daily amoxicillin could eventually become an alternative treatment option given its low cost, acceptable taste, and relatively narrow antimicrobial spectrum (4). While once-daily amoxicillin is supported by the AAP, both the AAP and IDSA currently recommend a standard 10-day course of either penicillin or amoxicillin as first-line treatment.

Penicillin allergic patients should be treated with a cephalosporin. For those patients with a Type 1 hypersensitivity to penicillins, the provider should consider clindamycin (20 mg/kg/day in 3 divided dosages, max 1.8 g/day). Macrolides are also acceptable alternatives for treatment, although macrolide resistance has been reported (15). The AAP does not recommend tetracyclines, fluroquinolones or sulfonamides for the treatment of GABHS penicillin-allergic patients who do not have immediate hypersensitivity-type reactions to penicillin is a 10-day course of a first-generation cephalosporin such as cefadroxil or cephalexin (1). Due to the relatively higher cost and wider spectrum of antibacterial activity of cephalosporins when compared to penicillins, however, this class of agents is not recommended for routine use in patients with GABHS pharyngitis who are not penicillin-allergic (1,4). Numerous once-daily and short-course antibiotic regimens have been approved by the Food and Drug Administration for treatment of GABHS pharyngitis in recent years. However, these regimens generally use unnecessarily broad-spectrum antibiotics and are less cost-effective when compared to penicillin; therefore, they are not recommended as first-line therapy (4,11).

It is important to acknowledge antibiotic treatment for GABHS is controversial. Many Western European countries do not treat

confirmed GABHS and there is no evidence of increased rates of ARF or other suppurative complications (16,17). Antibiotic prescribing trends in England over a 10-year period support a similar conclusion, where a 50% reduction in antibiotic prescriptions was not associated with an increased incidence of rheumatic fever. The decision to treat or not to treat depends on careful communication with parents about the pros and cons of treatment relative to the needs of the individual patient.

DISPOSITION

Most children with pharyngitis can be evaluated and managed as outpatients. For patients with airway obstruction or deep tissue abscesses, admission to monitored settings is recommended. An otolaryngologist should evaluate patients with confirmed abscesses to assess the need for surgical drainage. Admission should also be considered for those children who continue to refuse oral intake and require intravenous rehydration.

CRITICAL INTERVENTIONS

Acute Pharyngitis

- Assess and manage airway patency, hydration status, and pain.
- Always look closely (even in the uncooperative child) for oropharyngeal abscess.
- Diagnose and treat GABHS pharyngitis with appropriate antibiotics.

Common Pitfalls

Acute Pharyngitis

- Failure to obtain an adequate throat swab for RADT or culture.
- Failure to send a confirmatory throat culture if RADT is negative in children and adolescents.
- Failure to evaluate and document the airway examination.

CHAPTER 261

Croup and Other Upper Airway Disorders

Cristina M. Estrada and Timothy G. Givens

Infections of the upper airway are potentially life-threatening in that they may rapidly progress to obstruction, respiratory failure, and arrest. Inflammation of the supraglottic, glottic, or subglottic regions may produce laryngeal obstruction. Likewise, abscess formation may occur in the peritonsillar, retropharyngeal, or parapharyngeal spaces, leading to pharyngeal obstruction. Because of the confined spaces in which they occur, these entities share many clinical traits regardless of the offending organism.

Croup is a clinical syndrome characterized by a bark-like cough, hoarseness, inspiratory stridor, and respiratory distress of variable severity. The two most common forms are viral laryngotracheobronchitis (LTB) and spasmodic croup. The former is due to infection with parainfluenza viruses types 1, 2, and 3; respiratory syncytial virus; influenza virus type A; human coronavirus NL63 (HCoV-NL63); adenovirus; or rhinoviruses (1,2). The virus causes inflammation of the subglottic tissues and sometimes of the tracheal mucosa. The supraglottic structures are normal. Spasmodic croup is of uncertain etiology, is seen more commonly in patients with recurrent episodes of croup unaccompanied by infectious symptoms, and a family history of asthma, or allergies. Treatment of spasmodic croup ultimately does not differ from that of LTB.

The peak incidence of LTB is during late fall and early winter. It can occur in all age groups but is most prevalent during the second

year of life. There is a 2:1 male-to-female ratio, with a recurrence rate of 5%. Most cases of croup are mild to moderate and self-limited.

Epiglottitis, in contrast, is an acute life-threatening bacterial process. The epiglottis and the aryepiglottic folds become critically inflamed, while the glottis and subglottis remain unaffected. Epiglottitis is typically caused by *Haemophilus influenzae* type B (HIB); however, since the introduction of HIB vaccination the incidence of epiglottitis has declined precipitously among children (3). Epiglottitis occurs year round and can present in any age group, but it most often afflicts preschool children aged 2 to 6 years. Due to widespread HIB vaccination the burden of disease has shifted to older children, adolescents, and even adults. The onset is usually rapid, with a fulminant course leading to respiratory arrest from either airway obstruction or respiratory fatigue associated with a partial airway obstruction. When properly managed, the signs and symptoms of acute infection resolve within 24 to 72 hours. Epiglottitis does not recur following the first infection.

Bacterial tracheitis is a croup variant also known as *pseudomembranous croup.* This relatively uncommon illness occurs in children between 6 months and 8 years of age. Its distinguishing features are the presence of thick mucopurulent secretions. Although most commonly caused by *Staphylococcus aureus or* methicillin-resistant *Staphylococcus aureus* (MRSA), other pathogens such as *Streptococcus pneumoniae, Haemophilus influenzae,* α-hemolytic streptococcus, pneumococcus, and *Moraxella catarrhalis* have also been implicated (4). Owing to the evolution in treatment options including widespread immunization against *H. influenzae* type b and the use of corticosteroids for the treatment of viral croup, bacterial tracheitis has eclipsed croup and epiglottitis in terms of overall morbidity.

Infections of the retropharyngeal and peritonsillar spaces may range from cellulitis to frank abscess formation. Retropharyngeal abscess (RPA) typically afflicts patients younger than 6 years, probably because of the prominence of retropharyngeal lymph nodes in young children, which involute over time. RPA usually

develops by lymphatic spread, though extension from contiguous tissues, local trauma, or presence of a foreign body may be the inciting event. Peritonsillar abscesses represent extension of tonsillar infections and are more common in adolescents and adults rather than younger children. Both varieties of abscesses are polymicrobial in origin, with *S. aureus,* streptococcal species, and anaerobes the usual offenders (5).

CLINICAL PRESENTATION

LTB is characterized by a 1- to 2-day prodrome of coryza with a low-grade fever, followed by inspiratory stridor and the characteristic barking cough, with mild to moderate respiratory distress. Symptoms peak by 2 to 3 days, with respiratory distress worsening when the patient becomes agitated or cries; improvement and resolution is noted by 5 to 7 days (6). Patients presenting with wheezing, tachypnea, and stridor have a combined illness of bronchiolitis with overlying croup. Clinical scoring systems may assist physicians in assessing the degree and progression of respiratory distress (Table 261.1). In spasmodic croup, the same barking cough, stridor, and labored breathing are observed, but the patient is afebrile and does not have the upper respiratory symptoms preceding LTB. Patients with spasmodic croup are usually responsive to cool, humidified air and often improve by the time they reach the emergency department (ED).

TABLE 261.1
Comparison Between Epiglottitis and Laryngotracheobronchitis

Characteristics	LTB	Epiglottitis
Age	6 mos–3 yrs	2–6 yrs
Onset	Gradual	Rapid
Etiology	Viral	Bacterial
Swelling site	Subglottic	Supraglottic
Symptoms		
Cough voice	Hoarse cough	No cough Muffled voice
Posture	Any position	Sitting
Mouth	Closed; nasal flaring	Open-chin forward, drooling
Fever	Absent to high	High
Appearance	Often not acutely ill	Anxious, acutely ill
Radiograph	Narrow subglottic area	Swollen epiglottis and supraglottic structures
Palpation larynx	Nontender	Tender
Recurrence	May recur	Rarely recurs
Seasonal incidence	Winter	None

From Backofen JE, Rogers MC. Upper airway disease. In: Rogers MC, ed. *Textbook of Pediatric Intensive Care*, vol. 1. Baltimore, MD: Williams & Wilkins, 1987.

On the clinical disease spectrum, bacterial tracheitis lies between croup and epiglottitis. Similar to patients with LTB, bacterial tracheitis patients may have a viral prodrome; however, they may rapidly develop septic appearance with high fever and signs of upper airway obstruction. As opposed to epiglottitis, bacterial tracheitis patients often cough, are able to lie flat, and have no problems managing their secretions. Lastly, they often fail to respond to standard treatment for croup, including racemic epinephrine and systemic steroids (4).

Patients with epiglottitis typically have an abrupt onset of sore throat, high fever, and one or more of the “four D’s”: dysphagia, dysphonia, drooling, and distress. Inspiratory stridor may be audible, but there is usually no cough. Secretions, laryngospasm, and fatigue can further compromise breathing. Classically, patients assume a tripod sitting position, with the mandible extended forward in an effort to maintain airway patency. Patients appear very apprehensive and are often septic (3).

Both retropharyngeal and peritonsillar abscesses present with vague symptoms of fever and odynophagia which may evolve into a septic appearance. Patients with RPA may feed poorly, have stridor, exhibit difficulty handling secretions, and develop neck stiffness, pain or torticollis, all of which may combine to create a confounding picture consistent with meningitis. Those afflicted with peritonsillar abscesses may complain of unilateral ear or neck pain and speak with a "hot potato voice." Development of trismus is a clear clue to the presence of a peritonsillar abscess, and a unilateral erythematous bulge of the soft palate around the tonsil with uvular deviation away from the affected side is visible on inspection of the oropharynx (5). The absence of uvular deviation is an important pertinent negative in the evaluation of the adolescent patient with throat pain.

DIFFERENTIAL DIAGNOSIS

Atypical clinical features should prompt other considerations. Occasionally, a child with LTB caused by parainfluenza or influenza virus will present with stridor and wheezing and be diagnosed with bronchiolitis. Epiglottitis relative to croup is differentiated by its more acute and fulminant presentation (Table 261.1); in addition, a history of HIB vaccination does not entirely rule out epiglottitis. Ludwig angina, a rapidly spreading inflammation of the sublingual, submandibular, and submaxillary spaces (more common in adults) and retropharyngeal and peritonsillar abscesses are suspected based on careful inspection of the sublingual space and posterior pharynx. If membranes are noted in the oropharynx, diphtheria and infectious mononucleosis should be considered. Bacterial tracheitis is a primary consideration when a patient continues to deteriorate in spite of treatment or fails to respond to the standard management for LTB. Afebrile stridulous patients with a history of coughing or choking should be evaluated for possible foreign-body aspiration (see Foreign Body Chapter 273) (7). Patients with recurrent or persistent stridor or LTB during an atypical time of year should be considered at risk for the following diagnoses: congenital airway

anomalies, acquired tracheal stenosis secondary to previous intubations, congenital heart disease with associated vascular anomalies, tracheal hemangiomas, or recurrent angioneurotic edema.

ED EVALUATION

Croup is typically a clinical diagnosis; laboratory and radiographic studies are usually unnecessary (6). If the history and physical examination suggest LTB, the physician may apply a clinical scoring system to assess the patient's degree of compromise (Table 261.2). Sequential scoring is done after each intervention (8). An inspiratory soft tissue lateral neck radiograph and chest radiograph may be helpful in distinguishing LTB from other more ominous clinical entities (Fig. 261.1–Fig. 261.3). Classic radiographic signs of epiglottitis include the thumb sign (enlarged epiglottis), swelling of the aryepiglottic folds, blunting of the vallecula, and obliteration of the piriform sinuses. In LTB, the "steeple sign" (a gradual narrowing at the subglottic area) may be observed, however, all supraglottic structures should appear normal. The pseudomembranes of bacterial tracheitis, radiographically, may make the tracheal air column appear hazy. Radiographic widening of the soft tissue between the air column and cervical vertebrae is indicative of RPA or cellulitis. Since retropharyngeal cellulitis without abscess formation can be managed with antibiotics alone, a CT scan may prevent a surgical exploration for a stable patient in whom RPA was suspected.

TABLE 261.2
Clinical Croup Score

	0	1	2
Inspiratory breath sounds	Normal	Harsh with rhonchi	Delayed
Stridor	None	Inspiratory	Inspiratory and expiratory
Cough	None	Hoarse cry	Barking cough
Retractions/ flaring	None	Flaring, suprasternal retractions	As in 1 plus subcostal/ intercostal retractions
Cyanosis *or*	None	In room air	In 40% O_2
PaO_2 (mm Hg)	70–100	<70	<70
CNS function	Normal	Depressed/agitated	Coma

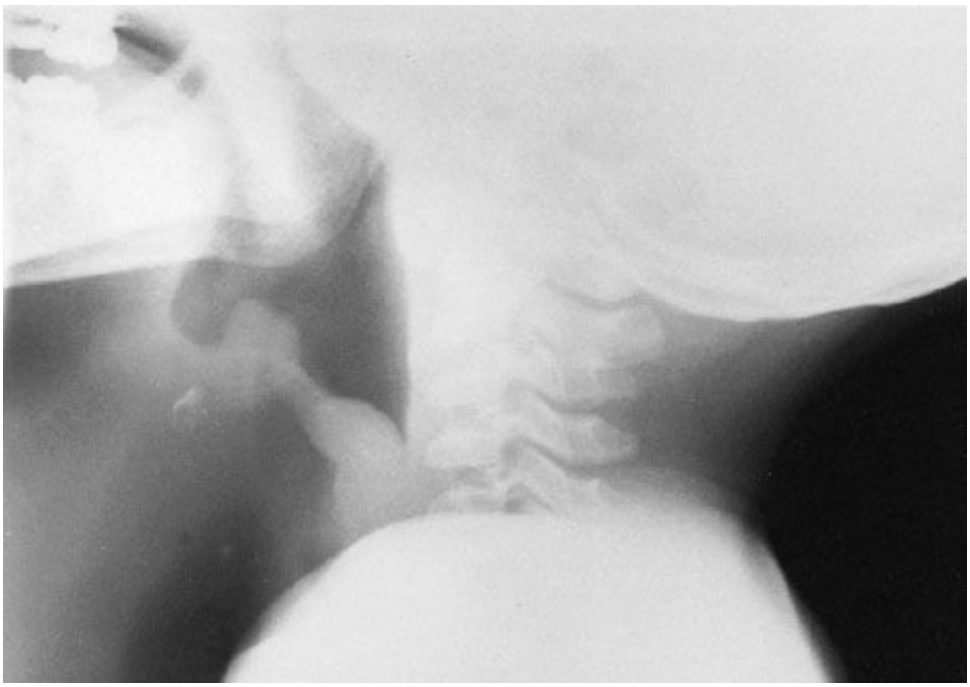

FIGURE 261.2 Epiglottitis on inspiratory soft tissue lateral neck radiograph. Supraglottitis.

FIGURE 261.3 Croup. Steeple sign on a soft tissue neck radiograph.

KEY TESTING

- Inspiratory soft tissue lateral neck radiographs may be performed when the diagnosis is in question.
- Chest radiographs can demonstrate the presence of a steeple sign in croup.
- CT scan with intravenous contrast may be helpful in delineating the extent of abscesses, in diagnosing complications, and in planning surgical intervention.
- Laboratory studies are of limited diagnostic utility in children with croup.

ED MANAGEMENT

Maintenance or provision of an adequate airway is the first priority in any illness in which airway obstruction is possible. A child in respiratory distress should not be separated from parental comfort unless respiratory arrest is imminent (6). Minimizing manipulation serves to reduce agitation and avoids increasing the child's work of breathing or worsening respiratory distress; for this reason venipuncture should be deferred if possible. The physical examination consists of inspection and observation at a comfortable distance from the patient. Oxygen should be delivered in a manner tolerable to the child. Strong subjective airway assessment skills are vital under these circumstances. When epiglottitis or critical tracheitis is established as the diagnosis, immediate arrangements should be made to transport the patient to an operating room for secure placement of an artificial airway. A physician experienced in airway management must accompany the child during transport to the operating room.

Each institution must establish an epiglottitis and critical tracheitis protocol that can be rapidly activated to mobilize personnel once these diagnoses are established (9). Patients with epiglottitis or critical tracheitis should be taken to the operating room immediately, where inhalational anesthesia is given with the patient in a sitting position (10). The hypopharynx is then visualized, and rapid intubation is performed with an endotracheal

tube 0.5 to 1 mm smaller in diameter than predicted for the patient's age and weight. A surgeon skilled in pediatric tracheostomy should be prepared to perform an emergency tracheostomy in the event attempts at intubation fail. Intravenous access and laboratory studies are usually obtained after induction of anesthesia.

For patients who present to the ED with impending or complete respiratory arrest, the airway must be addressed immediately in the ED. These patients may include those with more advanced cases of epiglottitis or tracheitis or LTB patients with croup scores >7. Bag-valve-mask (BVM) ventilation with 100% oxygen should be initiated. Higher positive pressures are sometimes necessary, requiring a two-handed technique to obtain an adequate chest rise. If these measures are unsuccessful within 15 to 30 seconds, a rapid oral intubation should be attempted. Ventilatory failure should be suspected in critical upper airway obstruction in patients who do not respond quickly to initial therapeutic maneuvers, who lose head control or become lethargic. Because of airway narrowing, an endotracheal tube size smaller in diameter than that predicted for the child's age and weight should be used if intubation becomes a necessity. Tips for intubating children with epiglottitis (or other types of critical upper airway narrowing) include using a smaller size endotracheal tube, using a stylet, and looking for an air bubble at the glottic opening while an assistant compresses the chest. If intubation is impossible, emergency cricothyrotomy or tracheostomy may need to be performed (see Chapter 218).

In milder cases of LTB, the treatment provided depends on the patient's level of respiratory distress. In mild cases (croup score <4), a trial of humidification therapy may be offered. However, no significant benefit of cool mist therapy has ever been proven, and a recent randomized, controlled trial of children with moderate croup failed to demonstrate the effectiveness of mist therapy in improving the clinical symptoms of croup (11).

There is ample evidence to suggest that corticosteroids are of benefit to patients with croup (12). Steroids promote resolution of laryngeal edema through their anti-inflammatory activity.

Dexamethasone (Decadron), 0.15 to 0.6 mg/kg, administered either orally or as a single intramuscular injection, has been shown to reduce the severity of symptoms, rate of hospital admissions, need for subsequent nebulized epinephrine treatments, and duration of hospital stay or observation in the ED (13,14). It reduces the number of return visits to the ED and speeds the resolution of symptoms in children with mild croup (13,14). Dexamethasone has a half-life of 54 hours, so one dose is usually sufficient. Inhaled budesonide has a rapid onset (within 2 to 4 hours) and has also been shown to be effective in mild to moderate croup (15).

Both oral and intramuscular routes of administration have been shown to be effective (12), and a randomized clinical trial comparing equivalent doses of intramuscular and oral dexamethasone showed no difference between the two in terms of clinical efficacy (16). The ease of administration of oral dexamethasone over nebulized or intramuscular agents makes the oral route preferable in most cases. The other routes become options in complicated croup requiring admission or associated with vomiting. As the effects of corticosteroid treatment may take up to 6 hours to appear, early administration is important. All patients who require epinephrine therapy should also receive steroids.

Patients with LTB and a clinical score ≤ 4 or inspiratory stridor at rest should receive oxygen and nebulized racemic epinephrine (0.05 mL/kg per dose [maximum dose, 0.5 mL] of a 2.25% solution diluted in 3 mL of saline and delivered with humidified oxygen, repeated as necessary) (8,17). Equivalent doses of either racemic epinephrine or (Levo) L-epinephrine have been shown to be equally effective (18). The L-epinephrine dose is 0.5 mL/kg of a 1:1,000 concentration to a maximum of 5 mL per dose. There should be almost immediate clinical improvement owing to reduction of edema and vasoconstriction of the inflamed mucosa through stimulation of the α-adrenergic receptors. Parents should be encouraged to deliver the nebulized treatment in a nonthreatening manner. Heart rate should be monitored during treatment with

nebulized sympathomimetics. The treatment should be stopped if the heart rate exceeds 200 beats/min or if dysrhythmias occur.

In the past, patients who received nebulized epinephrine were admitted to the hospital because of concern about a rebound effect, a clinical worsening thought to be due to vasodilatation and increased mucosal edema as the adrenergic effects abate. This phenomenon usually occurs within 2 to 4 hours after epinephrine treatment. Recently, the need for hospitalization has been reassessed; several studies suggest discharge from the ED is safe after 2 to 4 hours of observation, if the patient has no stridor at rest, normal air entry, normal color, and a normal level of consciousness (1).

Heliox, a combination of helium and oxygen gas, has a low viscosity and a low specific gravity and allows for greater laminar air flow through the respiratory tract (16). In clinical trials, heliox has *not* been shown to be more effective than humidified oxygen or racemic epinephrine in reducing croup scores (7,19).

Antibiotics are unnecessary for patients with LTB. Patients with epiglottitis or bacterial tracheitis should receive intravenous antibiotics as soon as IV access can be safely established. Epiglottitis can be treated with ceftriaxone (100 mg/kg/d at 12-hour intervals), cefuroxime (150 mg/kg/d at 8-hour intervals), cefotaxime (150 mg/kg/d at 8-hour intervals), or chloramphenicol (100 mg/kg/d at 6-hour intervals). Adequate coverage for *S. aureus* should be a consideration in cases of bacterial tracheitis. Bronchospasm and excessive secretions can be treated with β_2-agonist nebulization (e.g., albuterol) and suctioning. Additional supportive treatment includes antipyretics and intravenous fluids for patients with compromised oral intake.

Both retropharyngeal and peritonsillar abscesses are treated with intravenous antibiotics, with or without incision and drainage. Gram-positive and anaerobic coverage are standard. Antibiotic choices include clindamycin (30 mg/kg/d) or ampicillin–sulbactam (50 mg/kg per dose every 6 hours intravenously) (20).

CRITICAL INTERVENTIONS

- Have appropriate airway equipment available for the rare child with critical airway obstruction and respiratory distress.
- Administer oral or IM dexamethasone in a timely manner to all patients with LTB or spasmodic croup.
- Administer racemic epinepherine via nebulization to patients with stridor at rest, increased work of breathing, with a croup score >4.

DISPOSITION

LTB patients with a clinical score ≤ 4 (significant respiratory distress), those with persistent stridor at rest, and those with minimal or no response to treatment with nebulized adrenergic agents should be admitted, as should those with bacterial tracheitis and infections of the retropharyngeal space.

Instructions to parents whose children are sent home include monitoring the child's work of breathing (respiratory rate, retractions, and agitation), implementing a method of rapid and easy communication access between physician and family, and ensuring minimal physical exertion and stimulation during the convalescent phase of the illness.

Common Pitfalls

- Separating children from parents during initial assessment or during administration of nebulized medications or oxygen.
- Performing medical procedures (venipuncture, vital signs, laboratory, and x-ray studies) while patient is acutely symptomatic in lieu of administering steroids or nebulized epinephrine.
- Delaying the establishment of an artificial airway or not having the appropriate equipment readily available to manage the rare critical airway.
- Failure to consider bacterial tracheitis or RPA in a patient not responding appropriately to treatment.

CHAPTER 262
Pertussis

Adam Z. Barkin and Roger M. Barkin

Pertussis is a highly contagious respiratory illness, occurring in all age groups, but is particularly symptomatic in unprotected infants and children. Mortality and hospitalization rates are greater in preterm and unimmunized infants younger than 12 months of age (1). Neonatal pertussis, with maternal peripartum pertussis as the usual source, is particularly severe. The incidence of pertussis has decreased since the institution of the pertussis vaccine. However, there has been an increasing incidence of pertussis across the population, especially among adolescents and adults (2,3). In 2012, 51% of cases occurred in patients over the age of 11; whereas 10.8% were in infants less than 1 year of age (4).

Bordetella pertussis, a gram-negative pleomorphic bacillus, is the causative agent. Less frequently, a similar disease can be caused by *Bordetella parapertussis.* Transmission is by respiratory droplets, with extremely high attack rates (70% to 100%) in susceptible hosts. The incubation period is 5 to 21 days, with a mean of 7 to 10 days (1,5).

Although immunization reduces the incidence and mortality of pertussis, it is neither complete nor permanent. Immunity to pertussis wanes 3 to 5 years after vaccination. After 10 to 12 years, protection from vaccination is minimal (6–8).

CLINICAL PRESENTATION

The clinical manifestations of pertussis depend on age and previous immunization or infection. The classic illness, which lasts for 6 to 10 weeks, is generally divided into three stages: catarrhal, paroxysmal,

and convalescent. The course of the disease may be atypical, especially among adolescents and adults (3). Adult manifestations are often limited to rhinorrhea, sore throat, and persistent cough.

The *catarrhal stage* is characterized by nonspecific upper respiratory symptoms that may include rhinorrhea, lacrimation, mild cough, and low grade or no fever. This stage lasts 1 to 2 weeks, and the diagnosis is often not suspected. Patients are most infectious during the catarrhal phase.

In the *paroxysmal stage,* which may last from 1 to 6 weeks and up to 10 weeks, episodes of coughing increase in severity and number. A characteristic repetitive series of 6 to 12 forceful coughs during a single expiration is followed by a sudden, massive inspiratory effort that produces the classic “whoop” as air is inhaled forcefully against a narrow glottis. Cyanosis, bulging eyes, protrusion of the tongue, salivation, lacrimation, and distention of the neck veins may occur during episodes of coughing. The paroxysms can be precipitated by feeding, crying, or even hearing another person cough.

Physical examination during this stage may reveal conjunctival hemorrhages and petechiae over the neck and head. Some patients have diffuse rhonchi and rales on auscultation. In very young infants, the paroxysms and whoop are often absent with typical chief complaints of choking spells, apnea, bradycardia, cyanosis, and unresponsiveness.

In the *convalescent stage,* usually lasting 1 to 2 weeks but in some cases persisting up to 6 to 10 weeks, symptoms gradually abate (1,3,5,9,10).

Complications of pertussis include otitis media, failure to thrive, pneumonia, seizures, encephalopathy, epistaxis and other hemorrhages, cerebral hypoxia, and death. Most deaths due to pertussis occur in patients 6 months of age or younger (3,5,10). Pneumonia complicates pertussis in 5% to 20% of cases and may be due to *B. pertussis* or secondary bacterial infection. Apnea is a serious complication and is most common in children younger than 6 months of age. Other pulmonary manifestations include aspiration pneumonitis, subcutaneous emphysema, and pneumothorax. Seizures occur in 1% to 2% of cases, whereas encephalopathy occurs

in about 1% of cases (10,11). Of 100 deaths due to pertussis between 2000 and 2004, 90 were infants younger than 4 months, and 76 were younger than 2 months (1). Premature infants are at especially high risk for severe disease.

DIFFERENTIAL DIAGNOSIS

In classic disease, the clinical diagnosis of pertussis can be made without difficulty. Other infectious agents causing similar illness include *Mycoplasma pneumoniae, Chlamydia trachomatis, Chlamydia pneumoniae,* adenoviruses, respiratory syncytial virus, and other respiratory viruses. *B. parapertussis* and *B. bronchiseptica* occasionally produce a pertussis-like syndrome (5).

Spasmodic attacks of coughing may be observed in infants and children with bronchiolitis, bacterial pneumonia, cystic fibrosis, tuberculosis, an airway foreign body, and other diseases that cause lymphadenopathy and extrinsic compression of the trachea and bronchi.

Difficulty in recognizing pertussis occurs in the catarrhal stage, in mild illness, and in adults or very young infants where symptom complexes may vary widely. Pertussis should be included in the differential diagnosis of infants presenting with choking or apneic episodes and in children who present with a history of severe, spasmodic coughing or posttussive emesis.

ED EVALUATION

A child or infant suspected of having pertussis should be observed with formal monitoring for signs and symptoms of respiratory distress. Paroxysmal coughing episodes should be documented and the patient's hydration status should be carefully assessed. Between attacks, patients may appear normal and are usually in no distress. It is vital to remember young infants require hospitalization and close observation, in spite of looking well between paroxysms.

Diagnostic testing for pertussis is imperfect. Evaluation of the white blood cell count may be helpful; a leukocytosis of 20,000 to 50,000 cells/mm^3, with an absolute *lymphocytosis* (i.e. right shift), is

characteristic of severe disease. Chest radiographs are nonspecific and may show a perihilar infiltrate, atelectasis, or a "shaggy" heart border (10).

Culture of nasopharyngeal secretions remains the diagnostic gold standard when performed within the first 2 weeks of illness; false-negative results increase after 2 weeks. The test's specificity is reported to be 100% (3).

PCR is being used more frequently and if performed within 0 to 3 weeks of symptom onset has a reported sensitivity and a specificity of 94% and 97%, respectively (3). To optimize PCR test characteristics, the CDC has suggested a set of testing best practices, which include (1) testing only symptomatic patients, (2) being aware that testing after 4 weeks of cough or following antibiotics increases false-negative results, and (3) maximizing DNA recovery by obtaining samples via aspiration or posterior nasopharyngeal swab (12,13).

Finally, serologic testing can be used for diagnosis, but only in the later stages of disease (2 to 8 weeks after the onset of cough) (12).

KEY TESTING

- CBC: predictive of severe disease with leukocytosis >20,000 and a lymphocytic predominance or "right shift"
- Chest x-ray: with a perihilar infiltrate or "shaggy" heart border
- Culture of nasopharyngeal secretions: if within first 2 weeks of illness
- PCR of aspirated nasal secretions: if within first 3 weeks of illness and observing CDC best practices
- Serology: if between 2 to 8 weeks of symptoms

ED MANAGEMENT

In addition to watching for apnea, overall ventilation, and oxygenation should be carefully assessed and monitored. Patients should be observed both during paroxysmal coughing and between paroxysms. Suctioning the oropharynx with a catheter large enough to permit aspiration of tenacious secretions may be helpful during

paroxysms. Apneic infants may require active airway management. Children younger than 6 months old are more likely to be hospitalized, tend to have longer hospitalizations, and are more likely to require intensive care monitoring.

The paroxysmal coughing episodes may prove exhausting, and avoiding factors that provoke such attacks may be helpful. Early recognition of hypoxia or bradycardia is critical. Corticosteroids and bronchodilators such as albuterol are not routinely recommended for treatment of pertussis, although some have suggested they may reduce paroxysms of coughing (3). Maintenance of hydration and nutritional status is of utmost importance for optimal recovery, especially in infants with severe disease or posttussive vomiting.

Antimicrobial agents, if given early during the course of illness, may ameliorate the symptoms. Because of delays in definitive diagnosis, empiric treatment is often started early in the illness course. However, once paroxysmal coughing is established, antibiotics have no effect on the course of illness, but are still recommended to limit transmission. Macrolide antibiotics are the first line of treatment. Erythromycin was the traditional first-line choice, but azithromycin and clarithromycin are equally effective and have fewer side effects (5). In addition, administration of erythromycin has been associated with pyloric stenosis in infants aged 1 month and younger (10,14,15). For patients allergic to macrolides, trimethoprim–sulfamethoxazole is an acceptable alternative. See Table 262.1 for dosing guidelines (14).

TABLE 262.1
Antimicrobial Treatment Guidelines for Pertussis

Azithromycin	Children <5 mos 10 mg/kg daily for 5 d
Azithromycin	Patients >5 mos 10 mg/kg (max 500 mg) on day 1 5 mg/kg (max 250 mg) daily on days 2–5
Clarithromycin	15 mg/kg/d (max 1 g/d) divided into two daily doses for 7 d
Erythromycin	40–50 mg/kg/d (max 2 g/d) divided into four daily doses for 14 d
Trimethoprim—sulfamethoxazole	8/40 mg/kg/d (max 320/1,600 mg/d) divided into two divided doses for 14 d (contraindicated for infants <2 mos)

From Shah S, Sharieff GQ. Pediatric respiratory infections. *Emerg Med Clin North Am*. 2007;25: 961–979.

In addition to standard precautions, droplet precautions are recommended for 5 days after initiation of effective antimicrobial therapy. Chemoprophylaxis is recommended for all household contacts, irrespective of age and immunization status. The treatment regimen for postexposure prophylaxis is the same as that to treat active disease (14).

With the resurgence of pertussis in adolescents and adults with diminishing immunity, there has been increased focus on vaccination maintenance. Two Tdap vaccines (Tetanus toxoid, diphtheria toxoid and acellular pertussis vaccine, adsorbed), Boostrix and Adacel, were licensed in 2005. The Centers for Disease Control recommends Tdap vaccination instead of Td in adolescents and adults who require tetanus vaccination for wound management. In 2012, the Advisory Committee on Immunization Practices (ACIP) expanded their recommendation to include immunizing adults over the age of 65. Either Boostrix or Adacel is acceptable (16). The dosage of Tdap is 0.5 mL IM (1).

Cocooning, or immunization of adults and adolescents who will be in close contacts with infants <12 months, is recommended with a standard dose of Tdap. ACIP also recommends Tdap for pregnant patients during *EACH* pregnancy. The vaccine may be given at any time during pregnancy but is preferred between 27 and 36 weeks to maximize the level of maternal antibodies. No risk has been

demonstrated to the administration of vaccine during pregnancy (17,18).

CRITICAL INTERVENTIONS

- Recognize that infants may not exhibit the classic "whoop" of pertussis.
- Recognize that infants are at risk for apnea with pertussis.
- Treat all household contacts of patients with pertussis.
- Maintain current immunization status with Tdap throughout life.

DISPOSITION

Patients with severe disease and those younger than 6 months of age with significant clinical evidence of pertussis should generally be hospitalized because of the high rate of complications in this age group. The immunization history of siblings should always be reviewed. Older children and those with milder forms of illness may be discharged home after appropriate evaluation and initiation of antimicrobials. Parents should be instructed to call if breathing difficulties occur, if there is any evidence of cyanosis or restlessness, dehydration, or if medications are not tolerated. Close follow-up is essential.

Common Pitfalls

- Failure to recognize and diagnose pertussis, especially when it presents in an atypical fashion.
- Failure to recognize that infants younger than 6 months of age are at particular risk for severe illness.
- Failure to administer chemoprophylaxis to contacts.
- Incorrect specimen collection and delay in plating secretions on appropriate media.
- Failure to immunize appropriate patients with Tdap vaccine.

CHAPTER 263
Asthma

Jeffrey F. Linzer, Sr.

Asthma can simply be defined as recurrent reversible bronchospasm due to a trigger (Table 263.1). There is an underlying complex of inflammatory and neural mechanisms that make the airways more sensitive to the triggers and result in bronchial hyperresponsiveness and varying degrees of multicellular inflammation. Recruitment and activation of mast cells, macrophages, dendritic cells, neutrophils, eosinophils, and T-lymphocytes result in an inflammatory and cellular infiltration into the airways, causing the airway epithelium to become fragile and denuded. The epithelial sub-basement membranes thicken, mucus production and viscosity increase, and endothelial leakage results in mucosal edema. Clinicians should avoid outdated terms such as extrinsic (allergic) and intrinsic (late onset) asthma and instead adopt the terminology set out by the National Heart, Lung, and Blood Institute and the Global Initiative for Asthma: Mild intermittent, mild persistent, moderate intermittent, and severe persistent (Fig. 263.1).

TABLE 263.1
Triggers of Asthma Symptoms in Various Age Groups

Adapted from Pearlman DS, Lemanske RF Jr. Asthma (bronchial asthma): Principals of diagnosis and treatment. In: Bierman CW, Pearlman DS, Shapiro GG, et al., eds. *Allergy, Asthma and Immunology from Infancy to Adulthood*. Philadelphia, PA: WB Saunders, 1996:492.

Level of severity (Columns 2–5) is determined by events listed in Column 1 for both impairment (frequency and intensity of symptoms and functional limitations) and risk (of exacerbations). Assess impairment by patient's or caregiver's recall of events during the previous 2–4 weeks; assess risk over the last year. Recommendations for initiating therapy based on level of severity are presented in the last row.

Components of Severity		Intermittent			Persistent								
					Mild			Moderate			Severe		
		Ages 0–4 years	Ages 5–11 years	Ages ≥12 years	Ages 0–4 years	Ages 5–11 years	Ages ≥12 years	Ages 0–4 years	Ages 5–11 years	Ages ≥12 years	Ages 0–4 years	Ages 5–11 years	Ages ≥12 years
Impairment	Symptoms	≤2 days/week			>2 days/week but not daily			Daily			Throughout the day		
	Nighttime awakenings	0	≤2x/month		1–2x/month	3–4x/month		3–4x/month	>1x/week but not nightly		>1x/week	Often 7x/week	
	SABA* use for symptom control (not to prevent EIB*)	≤2 days/week			>2 days/week but not daily	>2 days/week but not daily and not more than once on any day		Daily			Several times per day		
	Interference with normal activity	None			Minor limitation			Some limitation			Extremely limited		
	Lung function		Normal FEV_1 between exacerbations	Normal FEV_1 between exacerbations									
	➔ FEV,* (% predicted)	Not applicable	>80%	>80%	Not applicable	>80%	>80%	Not applicable	60–80%	60–80%	Not applicable	<60%	<60%
	➔ FEV,/FVC*		>85%	Normal†		>80%	Normal†		75–80%	Reduced 5%†		<75%	Reduced >5%†
Risk	Asthma exacerbations requiring oral systemic corticosteroids‡	0–1/year			≥2 exacerb. in 6 months, or wheezing ≥4x per year lasting >1 day AND risk factors for persistent asthma	≥2/year		Generally, more frequent and intense events indicate greater severity.			Generally, more frequent and intense events indicate greater severity.		
		Consider severity and interval since last asthma exacerbation. Frequency and severity may fluctuate over time for patients in any severity category. Relative annual risk of exacerbations may be related to FEV,*											
Recommended Step for Initiating Therapy (See "Stepwise Approach for Managing Asthma Long Term," page 7)		Step 1			Step 2			Step 3	Step 3 medium-dose ICS* option	Step 3	Step 3	Step 3 medium-dose ICS* option or Step 4	Step 4 or 5
								Consider short course of oral systemic corticosteroids.					
The stepwise approach is meant to help, not replace, the clinical decisionmaking needed to meet individual patient needs.		In 2–6 weeks, depending on severity, assess level of asthma control achieved and adjust therapy as needed. For children 0–4 years old, if no clear benefit is observed in 4–6 weeks, consider adjusting therapy or alternate diagnoses.											

FIGURE 263.1 Terminology set out by the National Heart, Lung, and Blood Institute and the Global Initiative for Asthma. (From National Heart, Lung, and Blood Institute, National Institutes of Health. Expert panel report 3: Guidelines for the diagnosis and management of asthma. NIH Publication No. 07–4051, Bethesda, MD: National Institutes of Health, 2007.) Key: EIB, exercise-induced bronchospasm; FEV, forced expiratory volume in 1 second; FVC, forced vital capacity; ICS, inhaled corticosteroid; SABA, short-acting

β_2-agonist. †Normal FEV1 /FVC by age: 8 to 19 years, 85%; 20 to 39 years, 80%; 40 to 59 years, 75%; 60 to 80 years, 70%. ‡Data are insufficient to link frequencies of exacerbations with different levels of asthma severity. Generally, more frequent and intense exacerbations (e.g., requiring urgent care, hospital or intensive care admission, and/or oral corticosteroids) indicate greater underlying disease severity. For treatment purposes, patients with ≤ 2 exacerbations may be considered to have persistent asthma, even in the absence of impairment levels consistent with persistent asthma.

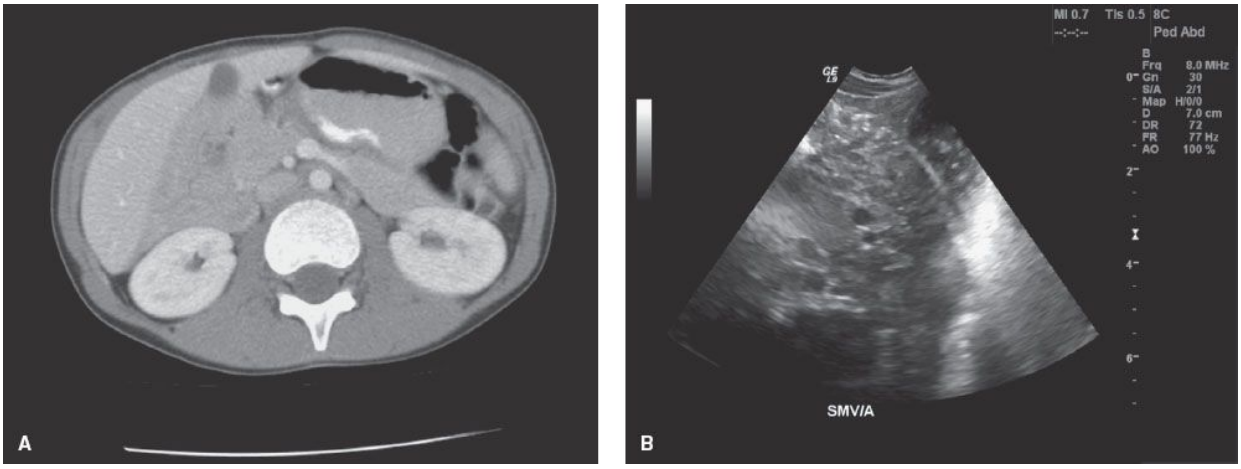

FIGURE 271.1 Images demonstrating position of the SMV in relation to the SMA. In patients with malrotation, the SMV is seen on the left of the SMA **(A)**. In normal orientation, the SMV will lie superiorly and to the anatomic right of the SMA **(B)**. This may be an incidental finding. (Image courtesy of Dr. John Lee.)

According to the Centers for Disease Control and Prevention, in 2011 over 10 million children were diagnosed with asthma. Non-Hispanic black children continue to be the most likely diagnosed (21%) as are children of poor families (18%) (1). Approximately 4.5% of all emergency department (ED) visits by children in 2010 were asthma related.

CLINICAL PRESENTATION

Acute asthma exacerbations vary widely in severity and duration. An asthma attack can be divided into two phases: Early and late allergen responses. The bronchospasm of the early allergen response (EAR) involves release of leukotrienes (LTC4, LTD4, and LTE4) and occurs soon after exposure to a provoking agent. About 50% of patients go on to develop a late allergen response (LAR) induced by a type 2 T-helper cell (Th2) about 4 hours after the initial trigger exposure. The LAR episode usually lasts 12 to 24 hours but may persist up to several days in some children.

Acute asthma attacks can be divided into mild, moderate, severe, and imminent respiratory arrest (Table 263.2). Classically, the child with an acute asthma exacerbation presents with wheezing and respiratory distress. Bronchospasm, however, can also present less characteristically as cough, chest pain, shortness of breath, and fatigue with exertion. There is poor correlation between symptoms, spirometry, and ventilation–perfusion measurements. Spirometry tends to reflect the degree of bronchoconstriction in large and medium airways, best measured by the forced expiratory flow 25% to 75% ($FEF_{25–75}$). Ventilation–perfusion mismatch is more related to obstructive changes in the peripheral airways.

TABLE 263.2
Evaluation of Severity of Asthma Exacerbation

	Mild	Moderate	Severe	Respiratory Arrest Imminent
Symptoms				
Dyspnea/Breathlessness	• Only with activity (assess tachypnea in young children) • Talks in sentences • Can lie down	• Interferes with or limits usual activity and talking (infant softer, shorter cry; difficulty feeding) • Speaks in phrases • Prefers sitting	• Present at rest; interferes with conversation • Able to say few words at a time (infant stops feedings) • Sits upright	• Unable to speak
Alertness	May be agitated	Usually agitated	Usually agitated	Drowsy or confused
Signs				
Respiratory rate	Normal to minimal	Increased	Marked	
0–17 mos	<40	40–60	>60	
18–35 mos	<35	35–55	>55	
3–6 yrs	<30	30–50	>50	
>6 yrs	<20	20–40	>40	
Work of breathing	Normal or mildly increased	Moderate accessory muscle use and retractions	Severe accessory muscle use and retractions	Paradoxical thoracoabdominal movement
		Nasal flaring may be present	Nasal flaring present	
Wheeze	Moderate, often only end expiratory	Loud; throughout exhalation	Usually loud; throughout inhalation and exhalation	Absence of wheeze, "quite chest"
Cough	No or mild cough	Frequent coughing but with no loss of breath	Frequent coughing with loss of breath	
Functional Assessment				
PEF				
% predicted or % personal best	≥70%	~40–69% or response lasts <2 hrs	<40%	<25%
PaO_2 (on room air)	Normal (test not usually necessary)	>60 mm Hg (test not usually necessary)	<60 mm Hg; possible cyanosis	
and/or				
PCO_2	<42 mm Hg (test not usually necessary)	<42 mm Hg (test not usually necessary)	≥42 mm Hg; possible respiratory failure	
SaO_2% (on air) at sea level	>90%* (test not usually necessary)	>90%*	<90%	
Clinical course	• Usually cared for at home • Prompt relief with inhaled SABA • Possible short course of oral systemic corticosteroids	• Usually requires office or ED visit • Relief from frequent inhaled SABA • Oral systemic corticosteroid; some symptoms last for 1–2 d after treatment is begun	• Usually requires ED visit and likely hospitalization • Partial relief from frequent inhaled SABA • Oral systemic corticosteroids; some symptoms last for >3 d after treatment is begun • Adjunctive therapies are helpful	• Requires ED/hospitalization; possible ICU • Minimal or no relief from frequent inhaled SABA • Intravenous corticosteroids • Adjunctive therapies are helpful

*A SaO_2 >90% is associated with a PaO_2 of 60 mmHg

Note: Hypercapnia (hypoventilation) develops more readily in young children than in adults and adolescents.

Source: Adapted and modified from National Heart, Lung, and Blood Institute, National Institutes of Health. Expert panel report 3: guidelines for the diagnosis and management of asthma. NIH Publication No. 07-4051, Bethesda, MD: National Institutes of Health, 2007.

With a mild attack, the child usually has been symptomatic for a short period of time and may still be in the EAR phase. There may be some increase in the respiratory rate, with a tight, hacking cough or end-expiratory wheezing. There is good air exchange, with minimal breathlessness and no accessory muscle use. A PaO_2 of 60 mm Hg or greater (reflected by a room air oxygen saturation [SaO_2] of >90%) is acceptable. Examination of lung function (peak expiratory flow rate [PEFR] or FEV in 1 second [FEV_1]) should be >70% of predicted or personal best.

In a more moderate attack, symptoms may have been going on for several hours to days, or unresponsive to treatment, indicating LAR. There is an increase in the work of breathing, with tachypnea and accessory muscle use. Expiratory wheezing may be audible from across the examination room, and inspiratory and expiratory wheezing may be present. The child may become breathless while talking and be somewhat agitated. An infant may have a less vigorous but more irritable cry and pull away from an offered bottle. Oxygen saturation is often in the low normal range, and PEFR/FEV_1 $<$70% of predicted or personal best.

Severe attacks are similar to moderate exacerbations in their time of onset and duration. There is marked respiratory distress, work of breathing, and tachypnea. Accessory muscle use is associated with intercostal and tracheosternal retractions and nasal flaring. Breath sounds can range from inspiratory and expiratory wheezing to a somewhat quiet chest. Emergency physicians must distinguish the child with minimal air movement, and therefore, no wheezing, from the examination of a healthy child with adequate air movement and no wheezing. Between these two extremes lies the child with an active asthma exacerbation, ranging from mild to severe, with audible wheezing. The child's mental status may range from anxious and agitated to somnolent and difficult to arouse, and tends to vary directly with corresponding degrees of air movement; worse air movement corresponds to a less desirable mental status. Infants will range from very agitated to unusually quiet and will refuse to take a bottle. Hypoxia is present, and the $PaCO_2$ may rise above 40 mm Hg. PEFR/FEV_1 is typically $<$40% of predicted or personal best.

It is important to remember that a child may present with symptoms from any and all of the mentioned categories, and that symptoms do not always lend themselves to easy classification. Emergency physicians must become familiar with the subtle nuances of respiratory distress that become appreciable only with frequent clinical reassessments.

DIFFERENTIAL DIAGNOSIS

The clinician's careful history and physical examination can help locate from which part of the respiratory tract the symptoms originate. Asthma is a diagnosis of exclusion in the first year of life and is uncommon during the second year.

Cough or rattling chest sounds that mimic asthma are most commonly heard with upper airway pathology. These sounds occur in children with an upper respiratory infection and in older children and adolescents with allergic rhinitis and sinusitis. Such conditions also may contribute to the severity of a subsequent asthma exacerbation. Similar sounds can be produced in infants with choanal atresia and in children with hypertrophy of the tonsils or adenoids. The examiner should be especially aware of potential foreign bodies in toddlers and young children.

Mid-sized airway pathology can cause not only cough but also wheezing and chest discomfort. Stridor, which is an inspiratory sound, must not be confused with wheezing. Examples of conditions producing stridor include croup, epiglottitis, and pharyngeal foreign bodies. Fortunately, epiglottitis in the post-*Haemophilus influenzae b* vaccination era has become rare in children, although group A streptococcus may produce a similar clinical picture. Unfortunately, laryngotracheobronchitis ("wheezy croup") and tracheal foreign bodies may also produce wheezing which must be distinguished from lower airway disease.

In infants, anatomic conditions causing cough and wheezing include laryngomalacia, tracheomalacia, tracheoesophageal fistula, and hemangiomas. Laryngeal webs, vascular rings, and slings are seen in older infants and toddlers. Vocal cord dysfunction is rare and usually noted only in older children and adolescents. These conditions share an important feature in that there is minimal, if any, improvement in symptom severity with conventional asthma therapy.

The lower airway causes of asthma-like symptoms are more difficult to differentiate from asthma. Cystic fibrosis can present with symptoms that initially respond to asthma treatments. Children with cystic fibrosis can go on to develop digital clubbing, which is rarely seen with asthma. Now less common owing to surfactant therapy,

bronchopulmonary dysplasia can occur in expremature infants who required prolonged ventilatory support. Chronic aspiration and gastroesophageal reflux, which can exacerbate underlying asthma, can produce cough and wheezing on their own. Inhalation of chemical and toxic substances and foreign bodies must also be considered.

Bronchiolitis (both respiratory syncytial virus [RSV] and non-RSV variants) is a common cause of wheezing in children younger than 2 years and especially in children less than 12 months of age. This disease occasionally responds to asthma treatment. Bronchitis should be considered an adult or adolescent disease at best. Chlamydia trachomatis (in infants younger than 3 months), pertussis (especially in infants younger than 6 months), pneumonia, and chronic *Chlamydia pneumoniae* in asthmatics can present similarly or aggravate underlying asthma.

Infections with aggressive forms of common respiratory viruses such as adenovirus and parainfluenza can lead to an asthma-like acute respiratory distress unresponsive to the usual asthma therapies. Infection with these agents can occasionally lead to acute respiratory failure. Other rare lower airway conditions to consider as causes of asthma-like syndromes include complications of congenital cardiac conditions, alpha$_1$-antitrypsin deficiency, pulmonary hemosiderosis, and pulmonary eosinophilia (Löffler syndrome).

ED EVALUATION

Determination of the severity of the attack is based on a rapid initial assessment that includes a brief history and directed physical examination performed in a calm and reassuring manner. Though baseline SaO_2 and measurements of lung function can be useful, the subjective findings on examination provide a better key to the severity of the exacerbation. Formally measuring pulmonary function in the ED may not be possible in many centers and should not be relied upon as a guide to management. Noting work of breathing, patient position and mental status, with frequent reassessment is the key to effectively manage acute asthma exacerbations. An SaO_2 of

<90% on presentation and remaining <91% 1 hour postpresentation, or a PEFR or FEV_1 <70%, can be used to determine severity and the potential need for hospitalization. Though children 5 years and older are capable of performing pulmonary function tests, studies have shown that only 65% can adequately perform one during an acute exacerbation (2).

The presentation and duration of symptoms and response to therapy prior to ED arrival, in addition to identifying contributing factors (e.g., fever, choking), may help to stratify the severity of an exacerbation and to determine the need for ancillary tests see Table 263.2. Assessment should also take into account the frequency and timing of previous episodes. Patients who have had multiple ED visits for asthma exacerbations, have required noninvasive positive pressure ventilation (NPPV), have been endotracheally intubated, have failed to properly use their rescue or controller medication, or have failed ED follow-up care in the past are at increased risk for severe exacerbations and should be treated aggressively.

The physical examination should rapidly determine the child's work of breathing by evaluating the degree of breathlessness, use of accessory muscles (including subcostal and intercostal muscles), and nasal flaring, and by listening to breath sounds. Simply noting the effort of breathing by watching the patient's exposed chest often yields of the most valuable clinical information. Neurologic status, reflected by the degree of irritability and responsiveness to the examiner and caretaker is an equally valuable marker of disease severity.

KEY TESTING

- Chest x-ray is not needed for straightforward asthma attack that improves with ED treatment. Order if there is concern for pneumonia, pneumothorax, or pneumomediastinum.
- Pulse oximetry and noninvasive end-tidal CO_2 monitoring.
- Routine CBC or blood chemistries do not provide useful information in uncomplicated asthma attacks.

ED MANAGEMENT

Short-Acting a-Agonists

Inhaled short-acting selective β_2-agonists (SABAs) remain the mainstay of acute asthma treatment. The inhaled β_2-medications have rapid onset with a maximal peak response at 20 minutes (3). Children respond well to doses higher than those routinely used in adults, and there is a significant relationship between albuterol dosing and improvement in pulmonary function (4). Higher doses and more frequent administration also lead to greater bronchodilation (5). Failure to employ aggressive beta agonist therapy early can result in an unnecessary prolonged ED course or unnecessary hospitalization. Side effects such as tachycardia, tremors, nausea, and vomiting tend to be dose related, but overall, the beneficial effects of beta agonists on acute bronchoconstriction far outweigh the risks of side effects.

β_2-Agents available in the United States include albuterol and levalbuterol for nebulization and albuterol, pirbuterol, and levalbuterol by metered-dose inhaler (MDI). Though part of the NLHBI Expert Panel recommendations, pirbuterol has not been studied in acute pediatric asthma; it is considered about half as potent as albuterol on an mgm-per-mgm basis.

While bronchodilators have traditionally been administered by intermittent small-volume nebulizer, metered-dose inhalers with spacers (holding chambers with a valve) (MDI-S) and continuous nebulization (CN) have both been shown to be at least as effective as small-volume nebulization. MDI-S is a convenient and cost-effective way to administer medication to children of almost any age and appears to have fewer side effects when compared to small-volume nebulization (6,7). Four to eight puffs of a short-acting β_2-agonist (SABA) should be given over a 2- to 5-minute period. CN has an advantage in patients with more severe presentations; doses of up to 30 mg of albuterol per hour can easily be administered to the patient with severe disease or impending respiratory failure (8).

The recommended dosing of inhaled β_2-agents is summarized in Table 263.3. While the question remains somewhat controversial,

there does not appear to be any clinical difference between racemic albuterol and levalbuterol in the acute setting (9).

TABLE 263.3
Dosing of Inhaled a_2-Agents

Medication	Method	Dose[a]	Interval[b]
Albuterol	MDI-S	4–8 puffs (30- to 60-sec intervals)	Every 20 min during the first hr
	SVN	0.15–0.3 mg/kg (2.5 mg minimum)	Every 20 min during the first hr
	Convenience dose	2.5 mg/dose ≤15 kg	
		5 mg/dose >15 kg	Every 20 min during the first hr
	CN	0.5 mg/kg/hr	Every 1–4 hrs
	Convenience dose	7.5 mg/hr ≤15 kg	
		15 mg/hr >15 kg	Every 1–4 hrs
Levalbuterol	MDI-S	4–8 puffs (30- to 60-sec intervals)	Every 20 min during the first hr
	SVN	0.075–0.15 mg/kg (1.25 mg minimum)	Every 20 min during the first hr
	Convenience dose	1.25 mg/dose ≤15 kg	
		2.5 mg/dose >15 kg	Every 20 min during the first hr
	CN	0.25 mg/kg/hr	Every 1–4 hrs
	Convenience dose	3.75 mg/hr ≤15 kg	
		7.5 mg/hr >15 kg	Every 1–4 hrs

CN, continuous nebulization; SVN, small-volume nebulizer; MDI-S, metered-dose inhaler with spacers.
[a]Higher doses of albuterol have been shown to be safe and may be more effective for very severe exacerbations.
[b]As indicated by the patient's response.

Subcutaneous (SQ) or intramuscular (IM) injections of epinephrine or terbutaline have no clinical advantage over the inhaled β-agonists and their use should be limited to patients with severe exacerbations and poor air exchange (3). As a selective β_2-agonist, terbutaline may have a theoretical advantage over the nonselective α-β epinephrine. The SQ or IM dose of terbutaline is 0.1 mg/kg up to a maximum of 0.25 mg, and for epinephrine (1:1,000 solution) 0.01 mL/kg (0.1 mL minimum, 0.3 mL maximum). Doses may be repeated at 15- to 20-minute intervals to a maximum of three doses. The only intravenous (IV) selective β_2-agonist available in the United States is terbutaline. While not FDA-approved, the injectable preparation has been used in children with impending respiratory failure. An IV loading dose of 10 μg/kg (maximum of 1,000 μg) is given over 10 minutes, followed by a maintenance infusion of 0.4 μg/kg/min. The dose is titrated in

increments of 0.2 μg/kg/min until desired respiratory effects are achieved or unacceptable tachycardia occurs. The usual effective infusion dose is 3 to 6 μg/kg/min. The most common side effects, tremors and tachycardia, are dose related.

Ipratropium

Ipratropium bromide is a quaternary ammonium derivative of atropine. This greatly diminishes its systemic absorption and side effects. Its anticholinergic activity does provide an additional mechanism of bronchodilation. By itself, ipratropium has a relatively slow onset but a prolonged duration of action when compared with the β-agonists. It is never given alone as the primary bronchodilator. There is a clinical advantage when given in multiple doses with albuterol in children (10), especially when there is a significant cough component and in moderate to severe attacks.

Ipratropium should be considered with each treatment during the first hour of care or the first three to four nebulizer treatments. Four to eight puffs by MDI-S may be given either as a separate inhaler after the SABA or in an inhaler premixed with albuterol. When used with a nebulizer, 0.25 to 0.5 mg should be combined with each SABA small-volume nebulizer dose or 0.5 to 1 mg in a CN.

Corticosteroids

Systemic corticosteroids (SCS) should be given within 1 hour of presentation to the ED in all but the mildest asthma exacerbations. All routes—oral, IM, and IV—are equally effective (11). The onset of anti-inflammatory activity in all is approximately 4 to 8 hours. Steroids are a vital aspect of treatment in LAR. They decrease inflammation during the acute phase of an asthma exacerbation, and also decrease the relapse rate during the first week after an exacerbation. The route of administration should be chosen based on the patient's condition, the ability to take oral medications, and the risk of noncompliance, which is an important contributor to relapse potential (12).

Prednisone and prednisolone are the most commonly used oral SCS. They are given in a dose of 1 to 2 mg/kg (60 mg maximum). Oral methylprednisolone should be considered in children who are on chronic home SCS therapy, as these patients may be relatively resistant to their baseline former medications. Certain brands of prednisolone are available in a more palatable base that makes it easier for the child to take the medicine. Oral dexamethasone (0.6 mg/kg, 16 mg maximum) may be used as an alternative, especially if compliance is an issue, since a 2-day course is as effective as 5 days of prednisone or prednisolone (13,14). Though not FDA-approved, the parenteral form may be mixed with a flavoring agent and given orally. Otherwise tablets are preferred since the available oral liquid preparations have a very low concentration (0.1 mg/mL) or high alcohol content (30% for 1 mg/mL solution).

Parenteral SCS should be considered for patients who are too ill to take the oral medication or for those in whom there are concerns about compliance. Dexamethasone (0.6 mg/kg, 20 mg maximum) may be given either IM or IV. A single dose of IM dexamethasone can be as effective as a 5-day course of prednisolone (15). Methylprednisolone may be given IM (acetate 10 mg/kg, 160 to 240 mg maximum) or IV (sodium succinate 1 to 2 mg/kg, 125 mg maximum).

Inhaled corticosteroids (ICS) (e.g., budesonide) used concomitantly with a continuously nebulized SABA should be considered for patients with moderate to severe exacerbations. Inhaled steroids provide additional benefits when used with systemic steroids during ED treatment (16). This includes fewer days with symptoms and a trend toward lower hospitalization rates. Though a variety of dosings have been studied, a single dose of 1.5 to 2 mg of budesonide appears to be beneficial.

Oxygen

Children with significant respiratory distress will benefit from oxygen, even those with a normal SaO_2. Low-flow oxygen (1 to 2 L/min) by nasal cannula is usually sufficient to reach the goal of

maintaining SaO_2 >90%. For children requiring higher oxygen concentrations, high-flow oxygen should be administered via a nonrebreather mask. Warm, humidified oxygen is preferable to avoid irritation of the respiratory tree.

Additional Therapies for Severe Exacerbations

Magnesium sulfate has become an increasingly used second-line medication for moderate to severe asthma exacerbations. A dose of 25 to 50 mg/kg of magnesium sulfate (2 g maximum) IV given over 20 minutes may be useful for children who have not responded to conventional therapy, though the higher range appears to be of greater benefit in children (17). Children do not generally require additional hydration or a baseline electrocardiogram.

Heliox (helium-oxygen mixture) has a lower gas density than air or oxygen. Although the role of heliox remains controversial, it is believed that the decreased airway resistance to flow and smaller size or respirable particles result in increased deposition of β_2-agonist in the airways. Children receiving CN driven by either a 70:30 or 80:20 helium:oxygen mixture showed greater clinical improvement than those using room air or oxygen (18).

Ketamine, a dissociative anesthetic, improves pulmonary compliance and decreases airway resistance in moderate to severe bronchospasm. Children tend to tolerate the doses needed to produce bronchodilation better than adults do. Dosing is controversial and an initial dose of up to 1 mg/kg may be needed (19). Maintenance drips should be reserved for pediatric intensive care settings. Side effects, including emergence reactions and hypertension, can be treated with benzodiazepines.

NPPV (bilevel positive airway pressure [BiPAP] or continuous positive airway pressure [CPAP]) have been shown to be an alternative to intubation in children with moderate hypoxia (20). Delivery of β_2-agonist via BiPAP in the ED can stabilize children who otherwise would require admission to the intensive care unit. In a child who has good but incomplete improvement after a CN, a single SVN delivered by positive end-expiratory pressure (PEP) may help

with opening the more distal airways and improve delivery of the medication.

Antibiotics

The routine use of antibiotics is of no benefit in the management of acute asthma. Antibiotics should be used when findings are consistent with pneumonia or other clinical bacterial infection, and are directed to the most likely organism (see Chapter 265, "Pneumonia").

CRITICAL INTERVENTIONS

- SABAs are the mainstay of acute asthma treatment. They should be used early and at frequent intervals (by MDI-S or by CN).
- Ipratropium added to SABA during the first hour is beneficial when there is a cough component or in moderate to severe exacerbations.
- Most children who present to the ED require corticosteroids, and they should receive it within the first hour of ED care.
- Additional treatments, such as magnesium and heliox, should be started early in severe exacerbations.
- Asthma is an inflammatory disease. Viral infections are an important trigger. There is no need to routinely use antibiotics unless there is clearly a bacterial focus of infection.

DISPOSITION

Patient disposition depends on the severity of the attack, the response to treatment, and contributing risk factors. It is important that the patient be reassessed after initial therapy and observed for an appropriate period for relapse before leaving the ED.

A child who has had a mild attack, required no more than one or two albuterol treatments, and whose PEFR or FEV_1 was not $<70\%$ may be sent to home after a short (30-minute) observation period. All other patients should be observed for at least 1 hour for signs of relapse. A child who is breathing comfortably, has no or minimal tachypnea with good air exchange and clear lung fields and who has

a room air SaO_2 >90% may be discharged home. However, certain children are at greater risk of fatal out-of-hospital asthma exacerbations even when they appear clinically well after treatment. Patients who should be considered at high risk include those who have (21):

1. Had three or more ED visits for asthma in the past 12 months
2. Had two or more hospitalizations in the past 12 months or one within the past month
3. Required admission to intensive care because of severity of previous exacerbations
4. Used two or more canisters of SABA in the past month
5. Not been compliant with previous post-ED follow-up and controller use

Admission should be considered for patients with an incomplete or poor response to therapy. This includes children who have a "normal" SaO_2 but still show signs of air hunger and who improve when given low-flow oxygen (clinical hypoxia). The decision to watch a patient in an observation unit or an inpatient ward depends on local policies and capabilities. Children presenting in impending or actual respiratory failure or who have deteriorated in the ED should be admitted to a pediatric intensive care unit.

Children who are discharged should be sent to home with sufficient medication to continue their therapy. The goal is to transition them from scheduled use of SABA to rescue use as quickly as possible (usually within 1 to 2 days) because of the risk of tachyphylaxis and undetected relapse. Children respond well to short courses ("bursts") of SCS and do not need to be "tapered" from the systemic steroid effects. Prednisone, prednisolone, or methylprednisolone is continued at 1 to 2 mg/kg (60 mg maximum) in one or two divided doses. The length of treatment is a 3- to 7-day course, depending on patient's severity and rapidity of response. A second dose of dexamethasone (0.6 mg/kg, 16 mg maximum) is also acceptable. Parents tend to prefer having to give just 1 day of medication, which may result in better compliance (22). The tablets are preferred for home use as the available oral liquid forms have a low concentration (0.1 mg/mL) or high alcohol content (30% for 1

mg/mL solution). Parents can crush the tablets and mix them into a small amount of food or chocolate syrup. A tapering dose of prednisone, prednisolone, or methylprednisolone should be used if the child has taken systemic steroids in the previous 30 to 60 days, has had three bursts in the past 6 months, or four bursts in the past 12 months. The taper should be over 7 to 21 days. The risks of using systemic steroids in children with active varicella (i.e., potential development of disseminated disease) must be carefully weighed against the benefits. Use of appropriate antivirals should be considered.

All children who receive SCS in the ED should be discharged with a 1-month course of low to moderate dose ICS (Table 263.4). It is a cost-effective means of decreasing the rate of relapse (23). Lack of controller medication use after ED care has been shown as a risk factor for near-fatal exacerbations (21).

TABLE 263.4
Daily Dosing of Inhaled Corticosteroids

Drug	Low Dose	Medium Dose	High Dose
Beclomethasone HFA 40 µg/puff 80 µg/puff (in 1–2 doses)	40–80 µg (1–2 puffs) (1 puff)	160–240 µg (4–6 puffs) (2–3 puffs)	>320 µg (≥8 puffs) (≥4 puffs)
Budesonide DPI 200 µg/dose (in 1–2 doses)	200 µg (1 inhalation)	400 µg (2 inhalations)	>600 µg (>3 inhalations)
Inhalation suspension for nebulization 0.25 mg/dose 0.5 mg/dose (in 1–2 doses)	0.25 mg (1 ampule)	0.5 mg (2 ampules) (1 ampule)	>1 mg (>4 ampules) (>2 ampules)
Flunisolide 250 µg/puff (in 2 divided doses)	500–750 µg (2–3 puffs) 160 µg	1,000–1,250 µg (4–5 puffs) 320 µg	>1,250 µg (>5 puffs) >640 µg
HFA 80 µg/puff	(2 puffs)	(4 puffs)	(>8 puffs)
Fluticasone HFA: 44, 110, 220 µg/puff DPI: 50, 100, 250 µg/dose (in 2 divided doses)	88–176 µg (2–4 puffs, 44 µg) 100–200 µg (2–4 inhalations, 50 µg) (1–2 inhalations, 100 µg)	176–352 µg (4–8 puffs, 44 µg) 200–400 µg (4–8 inhalations, 50 µg) (2–4 inhalations, 100 µg)	>352 µg (>3 puffs, 110 µg) (>2 puffs, 220 µg) >400 µg (>4 inhalations, 100 µg) (>2 inhalations, 250 µg)
Triamcinolone acetonide 75 µg/puff (in 3–4 divided doses)	300–600 µg (4–8 puffs)	600–900 µg (8–12 puffs)	>900 µg (>12 puffs)

Adapted from National Heart, Lung, and Blood Institute, National Institutes of Health. Expert panel report 3: Guidelines for the diagnosis and management of asthma. NIH Publication No. 07–4051, Bethesda, MD: National Institutes of Health, 2007.

Children should be sent to home with a written asthma treatment plan that details what treatment the patient received and how any continuing problems at home should be managed. Children 6 years and older should be sent home with a peak expiratory flow meter, to be used two to four times a day; the results are used to guide further treatment.

All children who have had an ED visit for asthma exacerbation should be referred back to their primary care physician or specialist for follow-up. At a minimum, the parent should make phone contact

within 24 hours of discharge to advise the physician of the child's progress.

Common Pitfalls

- Failing to provide early, aggressive treatment can lead to unnecessarily prolonged ED care or hospitalization. Children tolerate relatively higher and more frequent doses of inhaled bronchodilator than adults do.
- Assuming that all children who wheeze have asthma—the conditions are not synonymous. Be alert to other possible etiologies such as foreign-body aspiration or laryngotracheobronchitis.
- Assuming that if a child is not wheezing, there is no asthma attack. Asthma can present as cough (cough variant asthma), chest pain, shortness of breath, and fatigue with exertion.
- Failing to understand which patients are at risk for near-fatal or fatal exacerbations.
- Failing to educate parents and children about potential triggers and how to avoid them. Smoking is a significant environmental trigger and is potentially harmful to the child, even if the parent "smokes outside."
- Failing to send the patient to home with ICS and directed follow-up with the primary care provider within a few days of the ED visit.

CHAPTER 264 Bronchiolitis

Esther M. Sampayo

Each epidemic season, the emergency physician is faced with evaluating, treating, and determining the disposition of infants and young children with bronchiolitis. The American Academy of Pediatrics defines bronchiolitis as “rhinitis, tachypnea, wheezing, cough, crackles, use of accessory muscles, and/or nasal flaring in a child less than 24 months” (3). Unlike children with reactive airway disease, the lower respiratory tract symptoms of children with bronchiolitis are caused by an acute infection causing inflammation of the bronchiolar epithelium. The resultant necrosis of epithelium causes plugging of the smaller airways by cellular debris, resulting in air trapping or atelectasis distal to the obstruction. This results in tachypnea, wheezing, rales, increased work of breathing, and potentially hypoxemia.

Respiratory syncytial virus (RSV) is probably the most important respiratory pathogen in young children and may cause serious morbidity and even mortality. It is the leading cause of infant hospitalization. While the overall hospitalization rates for bronchiolitis have dropped by 17% over the last decade, the number of cases in children with high-risk medical conditions (e.g., prematurity) increased by 34%, and the rate of mechanical ventilation increased by 21% (11,20). More than 50% of infants will acquire RSV infection during their first epidemic season, and 40% of these will progress from upper to lower respiratory tract illness. Three percent of all children <1 year of age will require hospital admission for bronchiolitis (20). The peak incidence of lower airway disease occurs in infants 2 to 5 months of age (9,20). The mean

annual mortality rate is estimated to be 2.8 per 100,000 births, with almost 80% of deaths occurring in patients younger than 12 months old.

Children in high-risk groups are at greatest risk for severe disease and death and require monthly immunoprophylaxis with palivizumab or RSV immunoglobulin during the RSV season. These include (1) those in the first few months of life with a history of prematurity ($\leq$35 weeks' gestational age), (2) those with congenital heart disease (CHD), (especially uncorrected pulmonary hypertension), (3) those who are immunosuppressed, and (4) those with chronic lung disease (CLD) (11,12). Environmental risk factors such as passive smoking, crowded households, and attendance at day care may contribute independently to disease severity.

There are two major subtypes of the RSV virus, strains A and B. Subtype A is commonly associated with more severe disease. Although RSV is the most common pathogen, other viruses, including parainfluenza type III, influenza, adenovirus, rhinoviruses, and mycoplasma, can also cause bronchiolitis (9). Human metapneumovirus (hMPV) is a newly described paramyxovirus associated with upper and lower respiratory tract symptoms similar to RSV bronchiolitis and is responsible for 5% to 10% of hospitalizations (24). Bronchiolitis caused by hMPV is usually found in older infants and is associated with a higher incidence of fever and atelectasis.

CLINICAL PRESENTATION

The presentation of the infant or young child with bronchiolitis ranges from the smiling, interactive child with mild tachypnea and end-expiratory wheezing to the child who presents with impending respiratory failure. Typically, there is a 3- to 5-day history of upper respiratory tract symptoms, including coryza and congestion, before the onset of lower respiratory tract symptoms. The parent may have noted that the child developed a "cold," is not as active, is breathing faster, or has difficulty feeding. Although most patients have tachypnea, cough, wheezing, and increased work of breathing, the

infant under 3 months may simply present with lethargy, irritability, or apnea and have few to no lower respiratory findings. Fever is often present early in the course of illness, but may be absent or low grade at the time lower respiratory tract symptoms develop. Lower respiratory tract involvement usually peaks within 3 to 5 days. Resolution of symptoms overall, including cough, wheezing, and mild hypoxemia, however, may take days to weeks.

DIFFERENTIAL DIAGNOSIS

Emergency physicians must be careful not to anchor on the diagnosis of bronchiolitis in infants during epidemic winter months and should consider other causes of lower respiratory tract illness. While bronchiolitis is a clinical diagnosis, children with atypical presentations, such as severe respiratory distress or absence of viral symptoms, may require more extensive diagnostic evaluation to investigate potential other causes. Congenital heart disease (CHD) and congestive heart failure are initially thought to be bronchiolitis, given that infants may present with symptoms very similar to those of bronchiolitis including poor feeding, tachypnea, rales, and wheezing. Congenital airway lesions, such as vascular rings, slings, teratomas, or bronchogenic cysts, may also present with symptoms suggestive of bronchiolitis. Aspiration from gastroesophageal reflux or tracheoesophageal “H-type” fistulas can cause symptoms precipitated by feeding that may mimic bronchiolitis. Other diagnostic considerations include congenital infections such as chlamydial or community-acquired pneumonia, foreign body aspiration, and allergic reactions. Recurrent symptoms should lead to consideration of cystic fibrosis, immunodeficiency, or asthma. It is often difficult to distinguish bronchiolitis from asthma (reactive airway disease) in older infants and children. However, the first episode of wheezing with upper respiratory tract symptoms in the young child should be considered to be bronchiolitis. Children with atopy, prior episodes of wheezing responsive to bronchodilator therapy, and a strong family history of asthma may indeed have asthma or be at increased risk of asthma (23). Children who have

wheezing beyond 12 months of age, are atopic, or have eosinophilia may be at increased risk of developing asthma as well (23). It is unclear whether children who develop lower respiratory tract illness have a predisposition to reactive airway disease or whether the viral infection itself causes pulmonary damage or immunologic changes leading to the development of asthma. On the other hand, repeated episodes of bronchiolitis are not uncommon, and infants who have had RSV bronchiolitis may be more prone to repeated episodes in the first year of life independent of their baseline risk for asthma. Therefore, in the absence of a strong family history, repeated wheezing episodes during the first year of life should be attributed to bronchiolitis and not asthma.

ED EVALUATION

No single fact or finding during emergency department (ED) evaluation is sensitive enough to predict which child will develop severe disease. A combination of history and physical examination findings is crucial in assessing any patient's risk for significant morbidity (Table 264.1). The history must include the gestational age at birth and whether there were any perinatal complications, such as CLD (formerly called *bronchopulmonary dysplasia*). As mentioned previously, underlying diseases or anomalies such as CHD, cystic fibrosis, or immunodeficiency, may also put the infant at increased risk. It is vital to determine whether the child is in the first few days of illness, in which case the disease may continue to progress and become more severe, or beyond the 3- to 5-day peak which marks the beginning of the convalescent stages of the illness. Social issues must also be considered as part of risk stratification, including the mother's ability to care for a sick infant or to return for additional care if the disease progresses.

TABLE 264.1
Risk Factors Associated with More Severe Disease

Moderate Risk	High Risk
Historic Factors	
Prematurity 34–37 wks	Prematurity <34 wks
Age <3 mos	History of cyanosis or witnessed apnea
Ill appearing on first 3 d of illness	Underlying condition:
	Pulmonary disease
	Congenital heart disease (pulmonary hypertension)
	Immunodeficiency
Physical Examination Findings	
General appearance: ill, not toxic	General appearance: toxic
Moderate accessory muscle use	Marked accessory muscle use
Respiratory rate: 60–70/min	Respiratory rate: >70/min
Oxygen saturation: <94%	Oxygen saturation: <90%
	Mottled, Prolonged capillary refill

The child's overall appearance is a sensitive indicator of disease severity. It is important to evaluate the respiratory rate, accessory muscle use for breathing, air exchange, and hydration status at presentation and after therapeutic trials. The oxygen saturation, as determined by pulse oximetry, is the single most objective predictor of more severe disease and should be measured on all infants and children presenting to the ED with bronchiolitis. Hydration status, as determined by physical examination (moistness of mucous membranes, capillary refill at the fingertip, presence or absence of tears), is crucial to assess since bronchiolitis-associated tachypnea accelerates insensible fluid losses and inhibits oral intake, sometimes leading to significant dehydration. Level of hydration as well as respiratory status play an important role in determining patient disposition.

Radiographs are not routinely indicated in infants or young children with bronchiolitis unless an alternative diagnosis is suspected or when there is severe disease. The majority of routine bronchiolitis radiographs show some degree of hyperaeration or peribronchial thickening (19). Infiltrates occur in $<10\%$ of children presenting for outpatient evaluation; the risk of airspace disease appears to be greater in children with oxygen saturation $<92\%$ or

severe distress. There is limited and controversial evidence that atelectasis on a chest x-ray correlates with progression to severe disease. More importantly, though, routine radiography may actually increase unnecessary use of antibiotics when atelectasis is misinterpreted as an infiltrate (19,25).

Evaluation of fever in infants younger than 2 or 3 months of age should be performed as per usual practice (see Chapter 222). Although the rate of bacteremia is low in infants with bronchiolitis, it may still occur in about 1% of RSV-positive infants. Furthermore, the risk of urinary tract infection is reduced in RSV-positive infants, but is still common enough to require screening (15). For infants older than 2 months of age with classic bronchiolitis, fever is unlikely to indicate serious bacterial illness and is more likely to be due to early viral illness, pneumonia, or otitis media (4,13,25). Therefore, routine culture of the blood or urine may be unnecessary. Complete blood cell counts are *rarely* useful and are weak screening tools. Microbiologic testing to determine viral etiology is indicated only for those with, or at significant risk of, severe disease (CLD, CHD) or for the purposes of infection control and isolation.

KEY TESTING

- Bronchiolitis is a clinical diagnosis based on history and physical examination findings. Chest radiography, blood tests, and viral testing are not routinely recommended for ED patients.

ED MANAGEMENT

To date, there is no strong evidence supporting the effectiveness of *any* single treatment for bronchiolitis (1,3,25). Most children presenting with bronchiolitis have mild or moderate severity of disease. Those with mild disease require only supportive therapy, which includes maintenance of hydration and respiratory support. Intravenous fluids may be required because of insensible losses due to respiratory distress, combined with poor oral intake. Normal saline boluses of 20 mL/kg and additional maintenance fluid may be required for those with signs of dehydration such as tachycardia,

sunken fontanel, and prolonged capillary refill. Oxygen supplementation is indicated if the patient's SpO_2 level is consistently below 90% or if the patient is in severe distress despite an adequate SpO_2. Suctioning may be helpful, but there is no evidence for the benefit of deep suctioning (3). There is some suggestion in the literature that nebulized 3% normal saline may be beneficial in breaking up secretions (14,25). The role of heliox in the management of bronchiolitis remains uncertain (3). Chest physiotherapy is not recommended.

The use of bronchodilators such as nebulized albuterol for bronchiolitis is controversial. (1,3,8). Clinical practice guidelines recommend that bronchodilators *not* be used routinely in the management of bronchiolitis. Although bronchodilators produce small short-term improvements in clinical scores, this must be weighed against the costs and adverse effects of these agents. Infants and children with bronchiolitis may undergo a trial of an inhaled bronchodilator, however—albuterol 0.15 mg/kg via nebulizer or 4 to 6 puffs via MDI with spacer and facemask. The effects should be assessed within 1 hour for objective improvement in oxygen saturation, lowering of the respiratory rate, or improved aeration. For those who do not improve, there is no need to continue further treatments (3). Nebulized racemic epinephrine has been considered more effective than β_2-agonists in several clinical trials and may be tried for those who do not respond to albuterol and will require hospitalization, but a number of recent studies do not support the routine use of epinephrine (3,8,10,21,25). A trial dose of 0.05 mL/kg of 2.25% epinephrine is an option for children who do not respond to albuterol, but treatment should not be continued in the absence of a clinical response within 1 hour.

Oral corticosteroids are not recommended in the treatment of bronchiolitis since there is no consistent evidence supporting their use (1,3,5–7,17,18,25). However, corticosteroids may provide some benefit in combination with racemic epinephrine and this suggests there may be a future role for them in combination with other therapies (17,25). Steroids should be considered for children with

multiple episodes of wheezing responsive to bronchodilator therapy, those with atopy, and those with a strong family history of asthma. Antibiotics are indicated only when a bacterial infection has been diagnosed, or for febrile neonates. Of note, more than 60% of children with bronchiolitis develop bacterial ear infections (4). Inhaled corticosteroids montelukast, cromolyn sodium, ribavirin, and immunoglobulins have all shown little evidence of clinical efficacy for bronchiolitis and are not recommended.

Children with moderate or severe respiratory distress should be allowed to assume a position of comfort, and 100% oxygen should be delivered. Suctioning of copious nasopharyngeal secretions may relieve some distress caused by airway obstruction. A trial of bronchodilators and/or racemic epinephrine should be delivered. Heated humidified oxygen administered by high-flow nasal cannula or nasal continuous positive airway pressure may be effective in preventing intubation and mechanical ventilation in severe cases of bronchiolitis (16). However, additional studies are necessary to determine what role these modalities should play in the management of severe bronchiolitis. Intubation is required for the child with severe respiratory distress or failure to respond to these measures.

CRITICAL INTERVENTIONS

- Use pulse oximetry to identify children with hypoxemia. This is the most specific and objective indicator of more severe disease. Cyanosis detectable on physical examination does not occur until the oxygen saturation is $<85\%$!
- Beware of dehydration, as infants with respiratory distress and copious secretions are at risk for poor feeding and have increased water losses due to fever and increased work of breathing.
- Suction the infant to help improve airway obstruction.
- Keep the infant in the position of comfort as long as possible and avoid agitating the patient.

DISPOSITION

Most infants and children with bronchiolitis do not require admission. Clearly, those in respiratory distress or with hypoxia or dehydration require intervention and admission. Among those with mild or moderate disease, no single factor can predict the need for admission (1,3,25). Children at high risk for developing more severe disease (see Table 264.1) should be considered for admission or close outpatient observation. Hospitalization should be strongly considered for infants at risk for apnea: premature infants younger than 37 weeks and <48 weeks after conception, full-term infants younger than 1 month of age, and infants with a prior apnea episode witnessed either by the family or the practitioner (23). Children who are early in the course of the illness or have moderate severity of illness that does not require admission should have follow-up arranged in 24 hours. Criteria for discharge include the following:

- No signs of severe respiratory distress.
- Caretaker is comfortable using bulb suctioning.
- Patient does not require supplemental oxygen.
- Patient's oral intake is adequate to prevent dehydration.
- Caretaker is comfortable and has resources available to take care of patient at home.
- Anticipatory guidance has been reviewed.
- Close primary care follow-up can be achieved.

Children with underlying medical conditions should have their subspecialist physicians consulted about treatment and indications for admission. For example, the pediatric cardiologist can determine whether the child with CHD has significant uncorrected pathology that creates a higher risk of deterioration. If the diagnosis of bronchiolitis is not clear, a pediatrician may offer further help with the differential diagnosis or workup.

Children with respiratory failure requiring intubation should be transferred to a facility with a pediatric intensive care unit. Children with underlying medical conditions or at high risk for severe disease

or mortality should also be transferred to a facility with pediatric subspecialists and a pediatric intensive care unit.

Common Pitfalls

- Failure to identify that the child is in the first few days of illness and may become progressively worse. Children who appear to have mild illness may progress over the next hours or days and thus require close outpatient follow-up. The caregiver should be given specific instructions of what to look for and when to return.
- Failure to assess the child's hydration status and to treat with intravenous fluid when indicated.
- Failure to identify the child with an underlying condition or a history of prematurity that put him or her at high risk for morbidity and mortality.
- Persistence in using bronchodilators despite no evidence of response. Less than 50% of infants with bronchiolitis respond to bronchodilators. If they have mild disease, they should be sent home with symptomatic care instructions and follow-up arrangements.
- Overuse of routine laboratory tests or radiographs in the infant or young child with bronchiolitis. Testing should be tailored to the individual patient.

CHAPTER 265 Pneumonia

Ian McCaslin

Pneumonia is an inflammatory process of the pulmonary parenchyma. It is commonly the result of community-acquired infections both viral and bacterial including *Mycoplasma pneumoniae* and *Chlamydophila* species (formerly known as *Chlamydia*). Although mortality rates from childhood pneumonia in the United States have declined over the past half century, worldwide pneumonia kills approximately 1.2 million children annually, making it the leading cause of death in children under the age of 5 (1,2). Pneumonia is frequently diagnosed in US children, with outpatient visit rates ranging from 74 to 92 per 1,000 children <2 years old to 35 to 52 per 1,000 children 3 to 6 years old (3). Children in the first 2 years of life have higher attack rates, but children in the 2- to 4-year-old age group have a higher incidence of pneumonia complicated by empyema (4).

Low socioeconomic status, poor nutrition, underlying disease, crowded living conditions, and smoke exposure as well as immunocompromise including malignancy, sickle cell disease, HIV, or genetic disorders have all been implicated in increased risk of pneumonia.

Pneumonia may be divided into bacterial and other etiologies (i.e., viruses, fungi, or parasites), but in the majority of cases a microbiologic agent is never identified. Since children do not produce sufficient sputum to obtain an adequate sample for culture, differentiation of infection from colonization is problematic. Nasopharyngeal culture is rarely useful in identifying a presumed bacterial pathogen. Rapid and reliable diagnostic methods are rarely

available to the practicing physician. There are well-recognized seasonal variations in respiratory illness with late fall and winter peaks of lower respiratory tract illness due to viruses such as respiratory syncytial virus (RSV) and influenza A or B, but bacterial pneumoniae exhibit less seasonal variation.

A number of epidemiologic studies (5,6) have confirmed the importance of *Streptococcus pneumoniae* as the agent responsible for the majority of serious bacterial pneumoniae across all age groups beyond the newborn period. Introduction of the heptavalent pneumococcal conjugate vaccine in 2000, followed by the 13-valent vaccine in 2010, have resulted in dramatic reductions in the overall rate of invasive pneumococcal disease, including pneumonia in children <1 year of age (7,8). Rates of mixed infection of *S. pneumoniae* with either *M. pneumoniae* or *Chlamydophila pneumoniae* are relatively frequent in older children, suggesting that the historical classification of clinical pneumonia into "typical" and "atypical" categories should be discouraged. Viruses cause relatively more disease in younger infants and children, whereas *M. pneumoniae* and *C. pneumoniae* infections become more prevalent in the school-aged population. The most common viral agent is RSV, and evidence of coinfection of *S. pneumoniae* with RSV is common, particularly in younger children. Human metapneumovirus infection is a relatively common cause of respiratory infection in young children, with a spectrum of disease similar to that of RSV (9). *Staphylococcus aureus,* including community-associated methicillin-resistant *S. aureus* (CA-MRSA), causes abrupt and severe pneumonia and should be particularly considered during influenza season or in the presence of severe disease (10). *Mycobacterium tuberculosis* may cause pneumonia in healthy children and is often linked to high-risk exposures. Anaerobic bacteria may be implicated in a host who is susceptible to aspiration, particularly if there is evidence of abscess formation.

CLINICAL PRESENTATION

Symptoms and signs of pneumonia in children vary with age, duration of illness, and underlying condition rather than by bacterial versus viral etiology. Many children with early pneumonia do not have specific respiratory complaints and do not appear severely ill. The “classic” presentation of sudden onset of fever, chills, chest pain, and productive cough is very rare. In fact, febrile children who are ultimately found to have pneumonia frequently present with nonspecific historical and physical examination findings (11). Infants younger than 2 months of age may present with fever and tachypnea and no signs of pulmonary consolidation or clinical evidence of sepsis. Young children usually exhibit some combination of fever, tachypnea, and focal lung findings, associated with a chief complaint of cough, upper respiratory infection symptoms, decreased activity, and poor intake. Older children typically demonstrate a short period of prodromal symptoms, including rhinitis, low-grade fever, decreased appetite, and decreased activity. The proportion of cases of pneumonia due to *M. pneumoniae* and *C. pneumoniae* increases in children after 5 years of age (12). Infections with these organisms characteristically progress slowly over 3 to 5 days, with fatigue, sore throat, low-grade fever, and cough. Occult bacterial pneumonia presenting with abdominal pain, vomiting, and dehydration may be mistaken for acute appendicitis.

Few findings on physical examination exhibit good interobserver reliability. No single physical examination finding or combination of findings demonstrates adequate sensitivity for the clinical identification of pediatric pneumonia. Fever, respiratory rate, and pulse oximetry are objective, reproducible parameters that may help in the clinical diagnosis of pneumonia, and most children with either bacterial or viral pneumonia exhibit some fever and cough by history or examination (11,13). World Health Organization criteria for the clinical diagnosis of pneumonia are based primarily upon the presence of tachypnea and retractions and demonstrate poor sensitivity for the diagnosis in a US-based population (14). The definition of tachypnea varies with age and is conservatively suggested to be a respiratory rate of >60 per minute in infants,

>40 per minute in young children, and >20 per minute in those 5 years and older. While the respiratory rate alone is a poor predictor of pneumonia, infants and children ultimately diagnosed with pneumonia are more often tachypneic than not (15). The presence of hypoxemia, defined as saturation <90% at sea level, is difficult to detect on physical examination (16). Given that hypoxemia is well established as a risk factor for poor outcome in patients with respiratory disease, the simple measurement of oxygenation by pulse oximetry should be included in the initial evaluation of all symptomatic infants and children.

Certain combinations of clinical findings are characteristics of complicated lower respiratory tract disease. Grunting respirations with fever are nonspecific but should prompt further investigation. Rales, retractions, and localized diminished breath sounds are highly correlated with parenchymal disease. The presence of an associated pleural effusion is suggested by unilateral decreased breath sounds and dullness to percussion.

DIFFERENTIAL DIAGNOSIS

A number of conditions may be mistaken for community-acquired pneumonia. Lower respiratory illness characterized by cough, rhinitis, fever, and either wheezing or dry crackles on examination in children younger than 2 years of age is characteristic of bronchiolitis. Caused principally by RSV and human metapneumovirus, bronchiolitis is not improved with antibiotics, and can run a protracted course over 1 to 2 weeks. Sudden onset of high fever and signs of pneumonia after several days of lower respiratory symptoms consistent with RSV should prompt concern for bacterial superinfection and warrants antibiotic treatment. More severe disease can present with cyanosis and signs of respiratory failure, particularly in infants with underlying medical conditions such as congenital heart disease. Reactive airways disease affects nearly 10% of children, and acute episodes of difficulty breathing and cough, particularly at night, are commonly triggered by viral respiratory infections.

Foreign body aspiration, heart disease, and other conditions may be mistaken for infectious pneumonia. A history of a choking episode should be sought in all young children presenting with suspected pneumonia.

Myocarditis is frequently initially misdiagnosed as pneumonia; an ill appearance that suggests pneumonia but is not accompanied by a diagnostic chest film should prompt clinical suspicion and an EKG, and possibly an echocardiogram.

Congenital heart disease is suggested by evidence of diminished peripheral perfusion, congestive heart failure, or evidence of poor growth on examination. Depending upon the specific defect, cardiomegaly on chest radiography or diminished pulse oximetry readings that do not respond to oxygen administration are often supportive of the diagnosis.

ED EVALUATION

In most instances the diagnosis of pneumonia is based upon the history and physical examination alone. A chest radiograph is not required but may be helpful in establishing the diagnosis and excluding noninfectious causes. Radiographs ordered empirically for febrile children younger than 10 years of age with no lower respiratory tract findings, signs of respiratory distress, tachypnea, or hypoxia will reveal an occult infiltrate in approximately 5% of cases (11). Extreme dehydration or early clinical presentation may lead to false negative chest radiography in children subsequently diagnosed with acute bacterial pneumonia.

Chest radiography does not establish the etiology of a community-acquired pneumonia in children. Diffuse peribronchial thickening with hyperinflation of the lungs from air trapping is, however, more consistent with bronchiolitis or a viral etiology in the younger child, whereas focal lobar consolidation and pleural effusion in the older child suggests *S. pneumoniae* or, less likely, *M. pneumoniae.* Chest radiographs should always be obtained in patients with suspected or documented hypoxemia who are in respiratory distress. Both blood culture and complete blood count (CBC) with differential should be

obtained for the hospitalized patient but are not routinely indicated in the outpatient management of pneumonia. The contribution of routine laboratory testing to patient outcomes can be variable. Knowledge of the peripheral white blood cell count or other acute-phase reactant levels at the time of presentation generally does not assist selection of specific therapy or consideration for admission (16). The prevalence of bacteremia is low, and most positive blood cultures are contaminants (17). Moreover, while bacterial disease is suggested by a peripheral white blood cell count $>20{,}000/mm^3$, the CBC does not reliably differentiate between specific etiologies of pneumonia.

ED rapid testing for influenza A and B viruses is recommended during seasonal outbreaks; a positive test can significantly reduce the number of laboratory tests and radiographs ordered, and likewise reduces the number of antibiotic prescriptions (18). Other diagnostic tests such as serology, antigen assay, PCR, and nasopharyngeal swab for culture are considered investigational and are of little benefit in clinical decision making in the outpatient setting (19). Thoracentesis and culture of pleural effusion should be reserved for ill-appearing children or those with immunocompromise who require critical care admission, and in cases where chest tube drainage or operative management is recommended for suspected empyema or abscess.

KEY TESTING

- Early pulse oximetry determination, and oxygen supplementation if $<92\%$
- Influenza A and B rapid diagnosis testing during seasonal outbreaks
- Chest radiography if more severe disease is suspected
- Complete blood count and blood culture if hospitalization is considered

ED MANAGEMENT

After a careful history and physical examination, coupled with a judicious use of radiography and laboratory markers, the emergency physician's primary tasks are to initiate therapy and determine patient disposition. Ill-appearing patients should be placed on continuous cardiorespiratory monitoring while in the ED and dehydrated patients with pneumonia should be given an intravenous (IV) saline fluid bolus of 20 cc/kg. Initial pulse oximetry readings $<92\%$ on room air or an ill appearance should prompt oxygen administration by non-rebreather mask until the response to therapy can be determined. A trial of bronchodilator aerosols may be considered for patients with associated wheezing or history of reactive airways. Antitussive agents are generally ineffective and are not recommended. Purified protein derivative (PPD) placement should be considered for all patients with newly diagnosed pneumonia.

CRITICAL INTERVENTIONS

Infants younger than 8 weeks of age should be hospitalized after culture of blood, urine, and CSF, and empiric administration of IV ampicillin and cefotaxime. Infants aged 8 weeks to 3 months with uncomplicated pneumonia should be admitted to the hospital after culture of urine and blood in the ED followed by administration of IV cefotaxime or ceftriaxone. Narrow-spectrum IV penicillin or ampicillin may be administered to fully immunized children requiring hospitalization in areas where local epidemiologic data demonstrate low-level penicillin resistance for invasive *S. pneumoniae*. Parenteral antibiotic therapy may be initiated with cefuroxime or ceftriaxone for hospitalized children who are not fully immunized, in regions of higher-level penicillin resistance, or for children with severe infections, including those with empyema (16). Inpatient treatment for infections suspected to be caused by either *M. pneumoniae* or *C. pneumoniae* may include IV azithromycin. Children with severe pneumonia require additional empiric coverage for *S. aureus* , including CA-MRSA. Initial treatment should include IV vancomycin in addition to IV

ceftriaxone. These children should be considered for admission to an intensive care unit. Emergency providers should maintain awareness of regional antimicrobial susceptibility reports.

DISPOSITION

Most children with pneumonia can be managed as outpatients, and antibiotic therapy is not indicated for patients with suspected bronchiolitis or if findings are consistent with a viral syndrome. Children beyond 3 months of age with uncomplicated pneumonia may be treated for 10 days with amoxicillin, cefuroxime, or clindamycin in penicillin-allergic patients (16).

For school-aged children where *M. pneumoniae* and perhaps *C. pneumoniae* are possible etiologic agents in addition to *S. pneumoniae,* macrolides including azithromycin or erythromycin are acceptable options. Though not approved for pediatric use, oral levofloxacin appears safe and effective in children with pneumonia if significant resistance to *S. pneumoniae* is suspected (20). Children in whom fluid intake or compliance is a concern may be given parenteral ceftriaxone (50 mg/kg as a single dose) for coverage of initial 24 hours of therapy.

Printed language-appropriate discharge instructions should be reviewed with caretakers prior to discharge from the ED. Attention to adequate hydration, fever control, medication compliance, and observation for worsening condition should be emphasized. The emergency physician may wish to communicate directly with the primary care provider prior to patient discharge. All children with pneumonia diagnosed in the ED should be reevaluated within 24 hours. Fever often persists for 48 hours into the course of treatment of bacterial pneumonia.

Indications for admission include age younger than 4 months, respiratory compromise, persistent oxygen requirement, inability to retain oral fluids or medication, concerning underlying medical condition, and uncertain home environment. Patients with immunocompromise, large pleural effusion, respiratory distress, evidence of hypoxemia requiring FiO_2 greater than feasible in a

general care setting, or suspicion of CA-MRSA pneumonia should be admitted to an intensive care unit or transferred to a facility where appropriate monitoring and critical intervention is ensured.

Common Pitfalls

- Failure to diagnose a patient with foreign body aspiration or myocarditis.
- Treating for bacterial pneumonia in the young well-appearing wheezing child.
- Failure to ensure understanding of discharge instructions, including follow-up in 24 hours.

CHAPTER 266 Arrhythmias in Children

Syana Sarnaik

Pediatric patients present with three basic categories of rhythm disturbance—fast, slow, or absent. Asystole and bradyarrhythmias are primarily seen in resuscitation settings and are discussed in Chapter 217. This chapter discusses dysrhythmias unique to pediatric patients outside the realm of critical resuscitation.

SUPRAVENTRICULAR TACHYCARDIA

Paroxysmal supraventricular tachycardia (SVT) is the most common pediatric tachydysrhythmia, and may present to the emergency department (ED) in children of almost any age. Infants may tolerate SVT well for 12 to 24 hours, but if the rhythm is sustained for longer periods, signs of congestive heart failure (CHF) may develop (1). Manifestations of CHF in infants include irritability, tachypnea, and poor feeding and, in more severe cases, mottling and cyanosis. Once CHF develops, the infant's ability to compensate is compromised, and the condition can deteriorate rapidly. Older children may have chest pain, palpitations, syncope, fatigue, and dyspnea. In general, the longer SVT continues, the more severe the symptoms. Because of decreased diastolic filling time, tachycardia can lead to decreased stroke volume and therefore decreased cardiac output. Sustained tachycardia is also associated with increased myocardial oxygen demand and decreased time for diastolic myocardial perfusion. Thus, SVT can lead to CHF even after the tachycardia has resolved.

There are three main categories of SVT: AV reentrant tachycardia; atrial tachycardia; and junctional tachycardia. The majority of SVTs are due to reentrant tachycardia. Atrial tachycardias include atrial flutter (characterized by reentrant circuits within the atria), atrial fibrillation, and ectopic atrial tachycardia. Junctional tachycardia is exceedingly rare outside the immediate postoperative phase of open heart surgery.

The etiology of the SVT varies by age group. In infants, more than 50% is idiopathic, and 10% to 20% is associated with Wolff–Parkinson–White (WPW) syndrome (2). The remainder of cases occur after cardiac surgery or in association with congenital heart defects that predispose to SVT, such as Ebstein anomaly, single ventricle physiology, and congenitally corrected transposition of the great arteries. Older children are more likely to have WPW, concealed bypass tracts, or congenital heart disease. Young infants are more likely to present with CHF.

Electrocardiographic Findings

The typical electrocardiogram (ECG) of a patient with SVT shows a rapid rate, a narrow QRS complex, and an absence of identifiable P-waves (Fig. 266.1). In reentrant SVT, the circuit is usually too short to generate a substantial P-wave deflection or the P-wave may be buried in the QRS or T-wave. However, when P-waves are visible, the P-axis is usually abnormal. In reentrant tachycardia, the rhythm is usually regular, with a rate of 220 to 320 beats/min in infants and 150 to 250 beats/min in older children. If the rate varies over time, the rhythm is less likely to be reentrant and more likely to be sinus tachycardia secondary to fever, pain, agitation, dehydration, or possibly an ectopic atrial tachycardia.

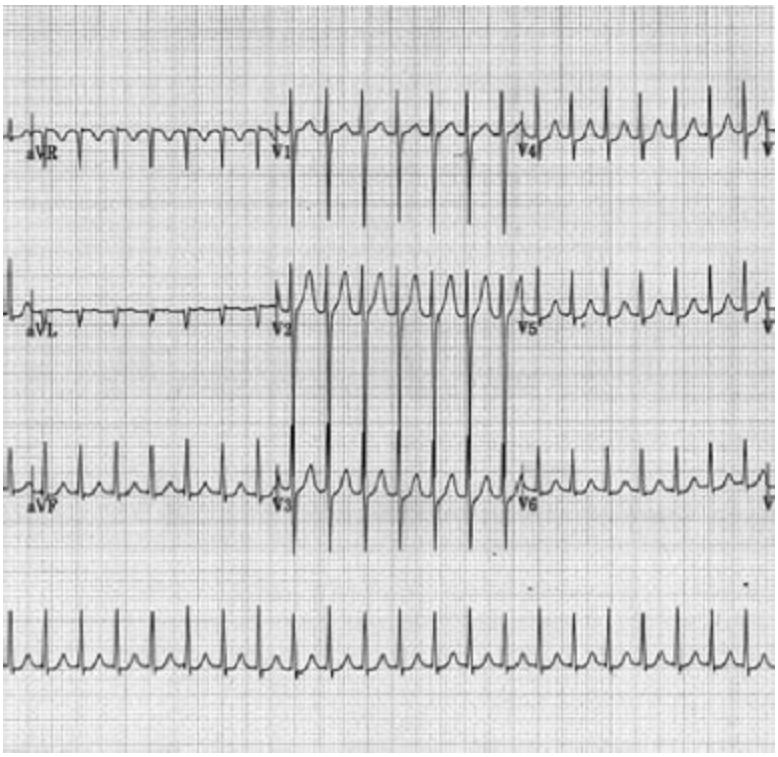

FIGURE 266.1 Supraventricular tachycardia.

ED MANAGEMENT

In an asymptomatic hemodynamically stable patient, the initial approach is to perform vagal maneuvers, followed if necessary by pharmacologic or electrical cardioversion. The effectiveness of vagal maneuvers is related to the patient's age, with the success rate lower in infants and young children (3,4). Nevertheless, the occasional conversion justifies their initial trial. For infants and young children, the application of a bag of crushed ice to the face (to induce the diving reflex) for up to 30 seconds is an effective vagal stimulus. Older children may be asked to blow into an occluded straw or to perform a Valsalva maneuver, which requires cooperation and usually a sustained effort of 15 seconds. Because of the risk of retinal detachment, ocular compression is not a recommended vagal maneuver. The majority of SVTs are reentrant and respond to intravenous adenosine (5). Since its hemodynamic side effects are typically mild and very brief, a diagnostic dose of adenosine can be

given safely if the type of underlying rhythm is not clear (Fig. 266.2).

FIGURE 266.2 Adenosine dose uncovering atrial flutter.

Adenosine causes transient AV block by hyperpolarizing the AV node. This may cause some patients to have an uncomfortable sensation but lasts only a few seconds. The initial recommended dose of adenosine is 0.1 mg/kg (initial maximum of 6 mg, followed by repeat doses of 12 mg) as a rapid bolus, followed immediately by a rapid flush of 5 to 10 mL of normal saline. Given adenosine's very short half-life of <1.5 seconds, it is important to use a three-way stopcock for a rapid flush immediately after the drug is administered. When administering adenosine, an ECG should be obtained prior to, and during, the conversion so as to document the underlying rhythm.

The patient may have a short break in the tachycardia due to adenosine followed by early recurrence requiring additional doses of adenosine. Infants may require up to 0.3 mg/kg by rapid intravenous push in a peripheral intravenous line, preferably positioned in the right arm. The adenosine dose can generally be lower if central venous access is obtained.

In general, calcium channel blockers are contraindicated in infants, as they may produce extreme bradycardia and hypotension in children younger than 1 year (6). In stable patients, other medications can be used, with input from a pediatric cardiologist. These include amiodarone (5 mg/kg), which slows AV nodal conduction and interrupts reentrant circuits, and procainamide (15 mg/kg over 15 minutes). Amiodarone and procainamide should not

routinely be given together, as hypotension and QT prolongation may occur. A pediatric cardiologist should also be involved after successful conversion of SVT for further management and prevention of recurrence. Since patients with SVT by definition have an acquired or anatomic defect of the conduction system, and since they may deteriorate rapidly, it is prudent to have equipment immediately available for airway management and defibrillation.

Immediate synchronized cardioversion with 0.5 to 1 J/kg is indicated if the patient is hemodynamically unstable. Cardioversion may not be successful in the presence of hypoxia or an acid–base disorder, so there should be careful attention to concurrent management of airway, breathing, and circulation (ABCs). Cardioversion can induce ventricular dysrhythmias in patients who are taking digoxin. In cases of digoxin-related ventricular arrhythmia, lidocaine can be used (1).

COMPLETE HEART BLOCK

Complete heart block may be either congenital or acquired. It may be associated with structural heart defects or occur postoperatively after repair of a congenital heart lesion, especially Tetralogy of Fallot (TOF) or ventricular septal defect (VSD). Maternal collagen vascular disease (e.g., lupus) may also result in transplacental passage of maternal immunoglobulins that result in an abnormal fetal conduction system. Infants typically present with bradycardia and a ventricular rate usually less than 75 beats/min. ECG findings include dissociation between atrial and ventricular depolarization and either a wide or a narrow QRS, depending on whether the escape beats are junctional or ventricular. The clinical presentation in infants may range from asymptomatic to frank CHF. Older children may have syncope, fatigue, and decreased exercise tolerance. In unstable patients, management focuses on stabilization of the ABCs and consideration of an infusion of isoproterenol (0.02 to 0.5 μg/kg/min) or epinephrine (0.05 to 0.5 μg/kg/min) to increase the junctional or ventricular escape rate, pending pacemaker placement. Improving AV nodal conduction with

atropine can be considered in first- and second-degree heart block but is not helpful in third-degree heart block. An external pacer should be applied while awaiting more definitive management.

VENTRICULAR DYSRHYTHMIAS

Isolated premature ventricular contractions (PVCs) may occur in up to 15% of normal newborns, 33% of normal adolescents, and 66% of patients with repaired heart disease (e.g., TOF, VSD, AV canal defects, transposition of the great vessels, and aortic stenosis) (7). An incidental finding of isolated PVCs is not worrisome, provided the remainder of the ECG is normal and the frequency of PVCs decreases with bedside exercise. However, multiform or complex ectopy (couplets, triplets), especially in an ill-appearing or febrile child, can be a presenting sign of myocarditis.

Ventricular tachycardia (VT) is defined as a series of three or more PVCs at a rate of 120 to 200 beats/min. QRS complexes are wide, and T waves have a polarity opposite the QRS. VT does not occur in children with normal hearts and usually indicates serious underlying myocardial pathology, dysfunction, or toxicity. Although uncommon, hemodynamically unstable ventricular arrhythmia requires immediate aggressive treatment. Cardiac output is seriously compromised in VT, and the rhythm is vulnerable to rapid deterioration to ventricular fibrillation. In the occasional patient who is stable, amiodarone should be given slowly, at a dose of 5 mg/kg over 20 to 30 minutes to avoid hypotension.

Unstable patients with VT require immediate synchronized cardioversion with 2 to 4 J/kg. Patients with pulseless VT require immediate defibrillation starting at 2 J/kg.

Electrolyte abnormalities should be considered in patients who are refractory to cardioversion. Drug ingestions causing dysrhythmias may require specific therapy (e.g., bicarbonate in patients with tricyclic overdose). In patients with digoxin toxicity, synchronized cardioversion should be avoided and treatment with digoxin-specific Fab fragments initiated.

ATRIAL FIBRILLATION

Atrial fibrillation is usually associated with structural heart disease such as dilated atria, myocarditis, digitalis toxicity, or previous intra-atrial surgery (e.g., Fontan procedure for hypoplastic left heart syndrome).

The ECG is characterized by an extremely fast atrial rate or a lack of recognizable atrial activity and an irregularly irregular ventricular response with narrow QRS complexes. Rate control can be accomplished by cautious administration of a beta blocker or calcium channel blocker. Digoxin may be started for longer-term control but is not effective acutely. In patients with atrial fibrillation and WPW syndrome, there may be rapid conduction to the ventricles and a risk of deterioration with drugs that preferentially slow AV node conduction, such as calcium channel blockers. Consultation with a cardiologist is strongly recommended (2).

For rhythm conversion, class I antiarrhythmic agents (i.e., quinidine, procainamide, flecainide) or the class III agent amiodarone may be used. Unstable patients require synchronized cardioversion, using 0.5 J/kg.

CRITICAL INTERVENTIONS

- Stabilize ABCs.
- Run a rhythm strip while administering adenosine to convert SVT.
- Be prepared for deterioration of dysrhythmia or patient's overall condition.

Common Pitfalls

- Rapid administration of amiodarone in stable patients.
- Failure to recognize complete heart block and failure to place a pacemaker as needed.
- Intravenous calcium channel blockers are almost always contraindicated in infants.

CHAPTER 267 Cardiac Murmurs

David G. Nelson

Heart murmurs are common in infants and children. Although most murmurs are benign, a few may be signs of serious heart disease, either congenital or acquired. The emergency physician must be able to determine which patients need emergency department (ED) evaluation, should be referred to their primary care provider, or be seen by a pediatric cardiologist.

CLINICAL PRESENTATION

Most cardiac murmurs are the result of normal turbulence and are therefore physiologic, also referred to as *benign, innocent,* or *functional.* In this case, the infant or child generally does not have signs or symptoms of systemic or cardiac disease. However, patients with pathologic murmurs may be ill-appearing or may have features of cardiac disease that must be evaluated and managed acutely in the ED. Evaluation begins with a thorough history and cardiovascular examination, including evaluation of murmur characteristics, peripheral perfusion, and associated signs and symptoms. It is unusual for a murmur to be the only sign of serious cardiac disease in a child without systemic signs or symptoms, with the exception of neonates or infants who have yet to display fulminant disease.

DIFFERENTIAL DIAGNOSIS

Benign Functional Murmurs

As the name indicates, these common benign murmurs of childhood are caused by blood flow within the normal heart (or by vibrations of

normal intracardiac structures) and share a number of common characteristics. They tend to be short, systolic not holosystolic, and soft and vibratory. In addition, they tend to vary with patient position, hydration status, and respiration. Patients have normal ECG and x-ray findings. These murmurs are often associated with particular age groups, locations in the chest, and other characteristics described in Table 267.1.

TABLE 267.1
Innocent Murmurs

Murmur	Approximate Age	Timing and Grade	Origin	Best Heard	Factors
Peripheral pulmonic stenosis (PPS)	Newborn–3 mos	Systolic ejection Soft grade 1–2/6	Bifurcation of pulmonary artery	LUSB–transmits to axillae and back	Increased with increased flow (anemia, fever, exercise, excitement)
Stills (vibratory) most common	3–6 yrs	Systolic ejection Grade 2–3/6	Vibration from left heart	Mid LLSB and cardiac apex	May disappear with Valsalva maneuver
Venous hum	3–6 yrs	Continuous Grade 1–2/6	Jugular vein and SVC	Supra and infraclavicular areas	Heard when patient is upright. Extinguished when patient is supine or head turned
Pulmonary ejection	8–18 yrs	Systolic ejection Soft grade 1–3/6	Pulmonary valve	LUSB	Increased with increased flow (anemia, fever, exercise, excitement)

LUSB, left upper sternal border; LLSB, left lower sternal border.

Pathologic Murmurs

Pathologic (or organic) murmurs are the result of turbulent blood flow through abnormal cardiac structures or vessels (Table 267.2). *Systolic murmurs* are due to either regurgitation or ejection. Regurgitation murmurs begin with the first heart sound (S1) and are caused either by insufficiency of an atrioventricular valve or by a left-to-right shunt through a ventricular septal defect (VSD). Ejection murmurs also start just after the S1 heart sound and are caused by a stenotic valve (see Table 267.2). *Diastolic murmurs* begin with the second heart sound (S2) and are caused either by the flow of blood from the aortic or pulmonary artery back into the ventricle, or by increased flow across a normal or stenotic mitral or tricuspid valve. These are almost always associated with underlying heart disease.

TABLE 267.2
Features Suggestive of a Pathologic Murmur

Any diastolic murmur
Systolic murmurs louder than 3/6, continuous, or associated with a thrill
Murmurs associated with clicks, rubs, abnormal splitting, or asymmetric pulses
Cyanosis or respiratory distress
Abnormal cardiac size or silhouette on chest radiograph
Abnormalities on electrocardiogram

ED EVALUATION

The evaluation of murmurs is largely based on clinical history and physical examination findings. More detailed historical elements appear in Table 267.3. It is vital to document whether a murmur is known to the family or patient and, if so, how long the patient had it and whether it has been evaluated by a cardiologist or treated surgically. Does the murmur result in associated symptoms such as poor feeding, edema, cyanosis, or shortness of breath? Does the older child have difficulty keeping up with friends while playing? Is there any family history of Marfan syndrome or sudden death?

TABLE 267.3
Questions to Ask Regarding a Patient with a Heart Murmur

Is it a known murmur? For how long? Has it been evaluated? Do you know what it is? How often does the child need to see the cardiologist? Has there been cardiac surgery?
Family history: Congenital heart disease, sudden cardiac death, Marfan disease
Associated symptoms such as edema, cyanosis, difficulty breathing, poor feeding, poor weight gain, congenital defects
Does the patient tire easily? Have trouble climbing stairs? Is the child unable to run during recess or gym class? Any syncopal or presyncopal episodes?
Recent illnesses (e.g., sore throat, viral infections) preceding the onset of murmur, especially in older children or adolescents. History of Kawasaki disease or syndrome

The murmur itself is characterized by four qualities: Timing, intensity, quality, and location. The timing is based on the murmur's relationship to the first (S1) and second (S2) heart sounds. Systolic murmurs are heard between S1 and S2, whereas diastolic murmurs are between S2 and S1. Continuous murmurs persist through S2. Murmur intensity (or loudness) is based on a scale of 1 to 6. Grades 1 to 2 are hardly appreciable, grades 3 to 5 are easily heard with a stethoscope, and grade 6 is audible with the stethoscope off the

chest. Murmur quality describes the murmur with such terms as musical, rumbling, harsh, vibratory, soft, blowing, or high-pitched. The location of the murmur on the chest is often helpful in establishing its etiology (see Table 267.4).

TABLE 267.4
Auscultation Locations of Common Systolic Murmurs in Children

Left upper sternal border: Pulmonic area
Pulmonic valvular stenosis
Atrial septal defects
Innocent pulmonic ejection murmur
Innocent peripheral pulmonic stenosis
Patent ductus arteriosus
Left lower sternal border
Innocent stills (vibratory) murmur
Ventricular septal defects
Endocardial cushion defects
Tetralogy of Fallot
Hypertrophic cardiomyopathy
Apex
Innocent stills (vibratory) murmur
Mitral regurgitation
Aortic stenosis
Hypertrophic cardiomyopathy
Right upper sternal border: Aortic area
Aortic valvular stenosis
Coarctation of the aorta

Associated signs and symptoms, beyond vital signs and oxygen saturation, can be helpful (Table 267.5). These include four-extremity blood pressures (looking for coarctation of the aorta). The routine physical examination of neonates and infants should include palpation for femoral pulses to detect otherwise occult cases of aortic interruption. In addition, clinicians should look for associated signs of heart failure, including edema, distended neck veins, liver enlargement, and respiratory distress. Dysmorphic features or evidence of growth retardation are other indicators that a murmur may be pathologic in nature.

TABLE 267.5
Associated Signs and Symptoms

Respiratory
Tachypnea or grunting may be a sign of failure
Auscultate for crackles
Fever
Consider infective endocarditis
May accentuate an innocent murmur
Cyanosis
Differentiate cardiac versus respiratory etiology
Assess for chronic hypoxia with clubbing of fingers
Pulses
Decreased, especially femoral
Cardiac failure
Cardiogenic edema is more likely to be pitting
Neck vein distention
Hepatosplenomegaly
Nutritional status
Poor weight gain or weight loss

KEY TESTING

- Neonates or infants (less than 6 months)—benign or pathologic murmur
  - Oxygen saturations, four-extremity blood pressures
  - Chest x-ray
  - If ill—cardiology consultation, echocardiogram
- Children and adolescents (pathologic murmur or systemic signs or symptoms of cardiac disease)
  - Oxygen saturation
  - Chest x-ray, EKG
  - Cardiac consultation or echocardiogram

ED MANAGEMENT

The management of a heart murmur detected in the ED depends on whether there are associated signs or symptoms suggestive of underlying cardiac disease. A number of ancillary diagnostic tests are available to aid in the diagnosis (Table 267.6).

TABLE 267.6
Ancillary Diagnostic Tests

Chest x-ray
Heart size and silhouette
Pulmonary vasculature (normal, diminished, or increased)
Electrocardiogram
Often normal
Dysrhythmias
Ventricular or atrial enlargement
Practitioner should be aware of significant differences in "normal" based on age
Blood tests
Complete blood count, sedimentation rate, blood culture, ASO (when considering rheumatic heart disease, endocarditis or Kawasaki syndrome)
Blood gases
Echocardiography
Provides definitive diagnosis
Not routinely used in emergency department except for ill patients or those with signs of heart failure or congenital heart disease

These tests need not be ordered routinely, but may be considered if the history and physical examination suggest a pathologic murmur. Some tests (e.g., chest x-ray and ECG) may be obtained as a baseline to help with assessment and to assuage parents' anxiety.

CRITICAL INTERVENTIONS

- Detailed history to identify historical or physical signs of heart disease.
- Consider infective endocarditis or rheumatic heart disease if a new murmur is noted in an older child with fever.
- Order an ECG and chest x-ray if any other signs or symptoms of pathology are present.
- If there is cardiomegaly on x-ray or the patient is ill-appearing, order a stat echocardiogram.

DISPOSITION

The emergency physician's primary goal is not to definitively diagnose the underlying lesion responsible for a murmur, but to assess the patient and provide a safe disposition. If it is determined a murmur is innocent, the child may be safely discharged home with

routine follow-up with the pediatrician or family practitioner. However, as with many conditions in pediatrics, the parents' anxiety may persuade the clinician that follow-up with a pediatric cardiologist is advisable. If it is suspected that the murmur is pathologic but the patient is clinically stable and the family is reliable, a call to the pediatric cardiologist is indicated to formulate an outpatient treatment plan, including prompt follow-up.

Common Pitfalls

- Failure to recognize a diastolic murmur, which is typically pathologic.
- Failure to recognize associated subtle signs and symptoms such as tachycardia, tachypnea, or failure to thrive as signs of serious heart disease.
- Failure to consult a cardiologist for pathologic murmurs.
- Failure to order an echocardiogram in an ill-appearing patient with a murmur.

CHAPTER 268

Congenital Heart Disease and Congestive Heart Failure

Ann M. Dietrich, Leslie Mihalov, and Katherine Mizelle

Congenital heart disease occurs in nearly 1% of live-born infants and must be recognized as early as possible in order to guide definitive medical and surgical management. At least 15% of congenital heart defects (CHDs) are associated with genetic conditions and about 20% to 30% of people with a CHD have other physical, developmental, or cognitive disorders (1). Routine neonatal examination fails to detect over half of infants with congenital heart disease. Many are discharged from the nursery before having a diagnosis made, and almost one-third of infants with critical heart lesions present to medical attention during the first week of life at the time of closure of the ductus arteriosus (2). Initial presentations range from the subtle (poor feeding) to the fulminant (shock or profound cyanosis), making congenital cardiac disease an important consideration in the differential diagnosis of any ill infant or young child. Congenital cardiac lesions can be classified by their mode of presentation and for the purposes of this chapter will be discussed in the following order: (1) cyanotic heart disease, (2) acyanotic heart disease, and (3) congestive heart failure (CHF).

CYANOTIC HEART DISEASE

CLINICAL PRESENTATION

Cyanosis is relatively infrequent in pediatric patients and is more commonly due to lung disease than heart disease. Cardiac lesions leading to cyanosis result from one of the three mechanisms: (1) obstruction of blood flow to the pulmonary circulation, (2) return of deoxygenated systemic blood back to the systemic circulation without passing through the lungs, or (3) inability of pulmonary venous blood to return to the left atrium and thence to the systemic circulation.

It is vital to differentiate between peripheral cyanosis (acrocyanosis, or discoloration of the extremities), which is particularly common in neonates (e.g., in a cold child or in a child with decreased peripheral perfusion), and central cyanosis (likely secondary to central nervous system depression, pulmonary disease, sepsis, metabolic disease, toxic ingestion, or cardiac disease).

The most common causes of cyanotic congenital heart disease are transposition of the great arteries (TGA), tetralogy of Fallot (TOF), tricuspid atresia, and obstructed total anomalous pulmonary venous return (TAPVR). Pulmonary atresia/critical stenosis and truncus arteriosus may also cause cyanotic congenital heart disease, but are less common and not discussed here. Table 268.1 lists typical radiographic and electrocardiographic findings in patients with cyanotic congenital heart disease.

TABLE 268.1
Cyanotic Congenital Heart Disease

Diagnosis	Chest Radiograph	ECG Findings
Tetralogy of Fallot	Normal/large heart with decreased PVMS "boot-shaped" appearance	Right ventricular hypertrophy, RAD (+120 to +150), right atrial hypertrophy
TGA	Mildly enlarged heart with increased PVMS "egg on a string" appearance	RAD, right ventricular hypertrophy
Tricuspid atresia	Normal/large heart with decreased PVMS	Leftward-superior axis, decreased right ventricular forces, LVH
TAPVR (with pulmonary venous obstruction)	Small heart with pulmonary edema	RAD, RVH

ED EVALUATION

The underlying physiology and presentations of cyanotic heart lesions, while seemingly complex, relies heavily on appreciating the importance of maintaining communication between the right- and left-sided circulatory systems in ductal-dependent lesions. Finally, the majority of children living with cyanotic heart disease as they progress through the course of multiple procedures have room air oxygen saturations of <90%. It is important to query caregivers about the patient's baseline oxygen saturations to have an informed sense of how to stratify the severity of a patient's current presentation (Table 268.1)

Transposition of the Great Arteries

TGA is the most common cyanotic congenital heart lesion to present in the neonate, and the second most common cyanotic congenital cardiac abnormality (6). It accounts for 5% of all congenital heart disease, and is more common in males. In a heart with D-transposition of the great vessels, the pulmonary and systemic circulations are isolated and in effect independent of one another, making a connection between the two systems via either an atrial/ventricular septal defect (ASD/VSD) or a patent ductus arteriosus (PDA) critical for survival.

Patients typically present in the newborn period with cyanosis and tachypnea but are not generally dyspneic. On auscultation, there is a loud, single S2. A systolic murmur may also be appreciated if an associated VSD is present or if there is pulmonary stenosis. Radiographically, TGA may present with mild cardiomegaly and increased pulmonary vascular markings, with a narrowed mediastinum ("egg on a string" appearance), but the majority of newborns with TGA have a normal-appearing chest x-ray. The electrocardiogram (ECG) is generally not diagnostic, showing the expected rightward axis and prominent right ventricular forces seen in neonates.

Management focuses on stabilization and allowing mixture of blood between the two circulatory systems. A prostaglandin E1

(PGE1) infusion can improve oxygenation by opening the ductus arteriosus to allow bidirectional mixture of the blood (see ED Management). Early involvement by a pediatric cardiologist is critical. Patients may require an emergent procedure for stabilization, such as a Rashkind atrial balloon septostomy, followed by definitive operative repair. Operations used for TGA include the Mustard, Senning, and arterial switch procedures. The arterial switch procedure is preferable because the right ventricle functions poorly as a normal systemic ventricle as the child ages, and there is a higher incidence of arrhythmias with procedures dependent on intra-atrial baffle procedures. To date, survivors of the arterial switch operation have much lower morbidity.

Tetralogy of Fallot

TOF is the most common form of cyanotic congenital heart disease beyond early infancy, representing 6% to 10% of all children with a CHD. Males and females are affected equally. The four defects comprising the tetralogy are: (1) VSD, (2) pulmonary stenosis, (3) right ventricular hypertrophy, and (4) overriding aorta.

In the newborn period patients typically present with a murmur. Clinical symptoms depend on the degree of right ventricular outflow tract (RVOT) obstruction. Initially, most infants are asymptomatic and only mildly cyanotic. As the RVOT obstruction progresses, the infant becomes increasingly cyanotic. Only about 25% of infants with TOF are markedly cyanotic at birth, and this subset can present in the first few days of life with acidosis due to severe cyanosis as a result of closure of the ductus arteriosus. On physical examination, the infant may have a right ventricular heave on palpation, a single S2 (pulmonic valve closure not heard), and a systolic ejection murmur at the left mid to upper sternal border (the intensity of which varies inversely with the degree of RVOT obstruction). A continuous murmur due to a PDA or collateral vessels may also be present. An ECG will generally demonstrate right axis deviation and right ventricular hypertrophy. A chest radiograph characteristically shows a normal heart size with decreased pulmonary vascular

markings, and a deficient main pulmonary artery segment resulting in a “boot shape” appearance of the heart.

Cyanotic or hypoxemic episodes “tet spells” are seen in some patients with TOF and typically consist of hyperpnea, irritability, and increasing cyanosis along with a decreased intensity of the underlying heart murmur. These episodes are frequently initiated by crying, and can also be precipitated by acute hypovolemia and tachycardia. During a “tet spell,” the murmur of pulmonary stenosis will markedly decrease in intensity. A decrease in systemic vascular resistance along with increased resistance to flow across the RVOT increases the right-to-left shunting across the VSD, which causes hyperpnea; the subsequent, increase in systemic venous return further promotes an increase in right-to-left shunting (see ED Management).

All patients with TOF will ultimately require surgical intervention. In a very young infant with severe RVOT obstruction and recurrent “tet spells,” palliative surgery to augment pulmonary blood flow involves surgical placement of a shunt, either a Blalock–Taussig shunt (subclavian artery to the ipsilateral pulmonary artery, or a central shunt [aorta to pulmonary artery]). Definitive surgical repair includes patch closure of the VSD and relief of the right ventricular outflow obstruction. A Rastelli procedure may be necessary in patients whose anatomy requires a conduit to bypass the RVOT obstruction.

Tricuspid Atresia

Tricuspid atresia has an incidence of 1% to 2% with no gender predominance. Children with tricuspid atresia, in addition to a missing valve, have a variable degree of underdevelopment of the right ventricle and pulmonic valve. Associated lesions include a VSD, pulmonary stenosis, and transposition of the great vessels. As there is no flow from the right atrium into the right ventricle, an ASD as well as a VSD are critical for survival in the newborn. If there is significant pulmonary stenosis present, a PDA is necessary to ensure adequate pulmonary blood flow. Common presentations

include severe cyanosis, poor feeding, and tachypnea. On physical examination there is a single S2, but patients with an accompanying VSD will have a grade 2–3/6 systolic murmur best heard at the left lower sternal border. Severe pulmonary stenosis will present with a loud systolic ejection murmur at the left upper sternal border. If a PDA is also present, the patient may have a continuous murmur and if there is obstruction to flow across the ASD, the infant will likely have hepatomegaly. The ECG has a characteristic leftward and superior QRS axis, along with evidence of right atrial and left atrial hypertrophy (RAH and LAH), as well as left ventricular hypertrophy. The chest radiograph will show a normal to slight increase in heart size along with decreased pulmonary vascular markings. Like all patients with abnormal development of two ventricles, these patients need multiple palliative surgeries to normalize oxygenation levels.

Ebstein Disease

Ebstein disease is a rare cause of cyanotic congenital heart disease, and consists of malformation of the septal and posterior leaflets of the tricuspid valve. Severe Ebstein disease presents in the neonate with marked cyanosis and tachypnea. The lesion is characterized on examination by a split S1, a triple or quadruple gallop, and a systolic murmur along the left mid to lower sternal border from severe tricuspid valve regurgitation. In severely cyanotic neonates, management consists of PGE1 to keep the ductus arteriosis patent until pulmonary vascular resistance decreases after infancy. Surgery in infancy is reserved for patients with persistent severe cyanosis and acidosis. After infancy, patients are generally asymptomatic with a variable degree of cyanosis. The ECG is notable for marked right atrial enlargement, and a right bundle branch block. Pre-excitation is seen in up to 25% of patients. The chest radiographic is pathognomonic, with massive cardiomegaly from right atrial dilation, and decreased pulmonary vascular markings.

Total Anomalous Pulmonary Venous Return

In TAPVR, the pulmonary veins bring the blood from the lungs to the right atrium instead of the left atrium. This entity may be divided into four anatomic groups, depending on the course of pulmonary venous drainage: (1) supracardiac, (2) cardiac, (3) infracardiac, and (4) mixed types. Patients with infracardiac drainage generally have significant pulmonary venous obstruction, and present with severe cyanosis and respiratory distress. In addition to pallor and decreased pulses due to decreased cardiac output, there is frequently hepatomegaly. The cardiac examination tends to reveal a loud single S2 with a gallop rhythm. The ECG demonstrates sinus tachycardia, right axis deviation, and right ventricular hypertrophy. A chest radiograph will show a small cardiac silhouette with pulmonary edema due to pulmonary venous congestion. Obstructed TAPVR is a surgical emergency, and immediate stabilization and repair is indicated.

KEY TESTING

- The hyperoxia test in patients with undifferentiated congenital disease
- Chest radiograph
- ECG
- Echocardiogram if available

ED MANAGEMENT

The initial management should focus on stabilization of the airway, breathing, and circulation. Once a diagnosis of congenital heart disease is suspected, a call to a tertiary care center, pediatric ED, or pediatric cardiologist is appropriate. If the child has a suspected ductal-dependent lesion, a PGE1 infusion should be initiated at a rate of 0.05 to 0.1 μg/kg/min. Adverse effects associated with PGE1 infusions include apnea (12%), fever, hypotension, and seizures. Because of the frequent occurrence of apnea, elective intubation should be considered prior to initiation of the PGE1 infusion.

The hyperoxia test. This is a useful bedside test to determine the etiology of a child's cyanosis (respiratory vs. cardiac). With the

application of 100% oxygen, an increase in pO_2 to >100 mm Hg suggests pulmonary disease, whereas a pO_2 <100 mm Hg suggests cyanotic congenital heart disease. The test can also be performed by measuring the oxygen saturation before and after the application of 100% oxygen, although this can be misleading because pulse oximetry is not as consistently accurate. The oxygen saturation should increase by at least 10% in the presence of a pulmonary process.

In patients with TOF and a hypercyanotic spell, a variety of maneuvers to improve oxygenation should be performed emergently. The child may benefit from being placed in the knee-to-chest position. All children should receive supplemental oxygen. Morphine sulfate at a dose of 0.1 mg/kg intramuscularly or subcutaneously may be given. IV access should be established, as these children are at high risk for recurrent episodes. An IV fluid bolus of 10 to 20 mL/kg may then be given. In refractory cases, phenylephrine 0.02 mg/kg IV should be considered to increase systemic vascular resistance and promote pulmonary blood flow. The dose may need to be titrated for effect. Sodium bicarbonate and propranolol may also be effective. In completely unresponsive cases, general anesthesia and paralysis may be considered. These children invariably require urgent surgical intervention.

ACYANOTIC HEART DISEASE

CLINICAL PRESENTATION

Acyanotic cardiac disease is composed primarily of lesions causing left to right shunting and left ventricular outflow tract (LVOT) obstructions. Lesions causing acute left to right shunting comprise almost 50% of all congenital heart disease and include (1) VSDs, (2) ASDs, (3) PDA, and (4) endocardial cushion defects. Infants with significant LVOT obstruction generally present in the first few weeks of life with symptoms of shock due to inadequate cardiac output after closure of the ductus arteriosus. The timing of presentation of a left-sided obstructive lesion depends upon the degree of obstruction

and upon ventricular function. The most common lesions presenting emergently are: (1) critical aortic stenosis, (2) critical coarctation of the aorta, (3) interrupted aortic arch (IAA), and (4) hypoplastic left heart syndrome (HLHS).

ED EVALUATION

Left–Right Shunts due to Structural Lesions

Depending on the degree of shunting from the systemic to the pulmonary side, consequences of significant pulmonary overcirculation can develop, including left ventricular dilation and hypertrophy, decreased ventricular function, and signs of CHF. In the neonate, high pulmonary vascular resistance initially limits the amount of left-to-right shunting, but as pulmonary vascular resistance drops in the first few weeks of life, pulmonary blood flow increases. Large left-to-right shunts (except ASDs) will eventually result in the development of pulmonary hypertension and the Eisenmenger complex if not diagnosed and surgically repaired in a timely fashion.

Clinically, patients will have a murmur characteristic of a specific defect. There is frequently a diastolic rumble or gallop. Pulmonary overcirculation may be the cause of the patient's tachypnea (with or without respiratory distress), pallor or mottling of the extremities, and underlie a history of feeding difficulties and poor weight gain. The differential diagnosis should include sepsis; however, the distinguishing features of the heart murmur, an S3 gallop, and enlarged heart on chest radiograph will help identify CHF in patients with shunt lesions. Pulse oximetry may demonstrate mildly decreased oxygen saturations due to pulmonary edema. Supplemental oxygen therapy should be used judiciously since it can accelerate CHF symptoms by lowering pulmonary vascular resistance and further enabling pulmonary blood flow.

Left-Sided Obstructive Lesions

Critical Aortic Stenosis and Critical Coarctation of the Aorta

The age of presentation of patients with aortic valve stenosis (AS) depends on the severity of the obstruction to flow across the aortic valve. Approximately 10% to 15% of patients present before 1 year of age (4). The typical presentation of severe aortic stenosis in infancy is CHF, but there can be cardiogenic shock in the setting of critical AS (ductal-dependent systemic blood flow). The latter patients present acutely and appear ashen, with markedly decreased or absent pulses, and are severely acidotic and obtunded. These patients may be cyanotic due to pulmonary venous desaturation. The classic murmur of AS is typically a loud and harsh systolic murmur with transmission to the neck. Patients presenting with severe aortic stenosis may have minimal, if any, murmur because of associated diminished cardiac output from ventricular dysfunction. Patients with reasonable cardiac output and aortic stenosis may also have an ejection click and a systolic thrill in the region of the upper right sternal border, suprasternal notch, or carotid arteries.

Infants with critical coarctation generally present before 2 weeks of age owing to progressive ductal closure and manifestations of obstructed arterial flow, whereas older children and adolescents with less severe coarctation may present with a murmur and hypertension that may have been longstanding in nature. Unlike patients with critical aortic stenosis who present with diminished pulses throughout, patients with severe or critical coarctation of the aorta and IAA should have unequal upper and lower extremity pulses (higher in the upper extremities). Four-limb blood pressures can be diagnostic. Simultaneous pulse oximetry readings in the right hand and a foot in patients with coarctation may show significantly lower oxygen saturation in the foot, due to perfusion of the lower extremities with desaturated blood from the PDA. A pulse oximetry reading in the leg of $<92\%$ on room air or more than a 7% difference between the leg and arm was found in 85% of infants with left heart obstructive disease and in 79% with other forms of congenital heart disease (5,6). ECG findings in critical aortic stenosis and critical coarctation are similar, with biventricular hypertrophy, ST-segment changes, and inverted T waves in lead V6.

The radiographic findings of patients with left-sided obstructive lesions vary. Infants who present in failure may have cardiac dilation and pulmonary venous congestion. Older children with aortic stenosis generally have a normal-appearing chest x-ray, and those with isolated coarctation of the aorta can have evidence of collateral blood vessels, characterized by rib notching.

Hypoplastic Left Heart Syndrome

HLHS accounts for 1% of all CHDs, and is more common in males. As in infants with critical coarctation of the aorta and critical aortic stenosis, systemic perfusion depends on a PDA. Clinical presentation after birth can initially be subtle, with no murmur, intermittent pallor, and a complaint that the infant is "not acting right." As the ductus constricts, tachypnea, respiratory distress, and metabolic acidosis occur. The closure of the ductus results in rapidly progressive cardiogenic shock and circulatory collapse. In addition, there can be significant obstruction to systemic blood flow if there is restriction of the obligatory left-to-right shunt across the patent foramen ovale. Surprisingly, infants with HLHS may have normal radiographic findings. ECG findings vary considerably but commonly there is RVH.

ED MANAGEMENT

The initial management should focus on acute stabilization of the airway, breathing, and circulation. Once a diagnosis of congenital heart disease is suspected, a call to the tertiary care center, pediatric ED, or pediatric cardiologist is indicated. Management of symptomatic shunt lesions is discussed in the next section on CHF. If there is concern regarding a left-sided obstructive lesion, initiation of PGE1 at 0.05 to 0.1 μg/kg/min may help to maintain patency of the ductus in an infant. The goal should be to maintain adequate systemic blood flow via the ductus without hyperperfusing the pulmonary vasculature. This balance can be achieved by methods to increase the pulmonary vascular resistance, such as controlled hypoventilation and positive end-expiratory pressure.Supplemental

oxygen should be limited, with acceptance of lower oxygen saturations, to avoid a dramatic drop in pulmonary vascular resistance. Sodium bicarbonate may be indicated in patients with severe acidosis. Prompt referral to a pediatric cardiologist or pediatric cardiovascular surgeon is indicated. Treatment may include staged or definitive surgery, or interventional cardiac catheterization (e.g., for aortic stenosis).

CONGESTIVE HEART FAILURE

CLINICAL PRESENTATION

Ninety percent of cases of CHF in children occur during the first year of life and it is frequently the final common pathway for congenital lesions that have progressed to critical stages. The CHDs most commonly associated with CHF are those that result in pulmonary overcirculation through a large left-to-right shunt (VSD, PDA, atrioventricular [AV] canal defect). Patients with significant shunts typically present between 3 and 8 weeks of age, following the physiologic drop in pulmonary vascular resistance, which allows pulmonary overcirculation to develop. The pathophysiology of CHF in these children starts with increased pulmonary blood flow and progresses to pulmonary interstitial edema, and volume overload of the left heart. A chest radiograph should be considered for any "first-time wheezer" who fails to improve with conventional treatment. Hyperinflation from bronchiolitis should be associated with a normal or small cardiac silhouette. Cardiomegaly in a child with wheezing suggests "cardiac asthma" due to cardiomyopathy, pericardial effusion, pulmonary overcirculation, or other cardiac etiologies. Children presenting with symptoms of CHF later in life should be suspected of having an acquired problem (e.g., cardiomyopathy) rather than a congenital heart disease. In contrast, CHF in the first day of life is usually secondary to cardiac muscle dysfunction from hypoxia, hypoglycemia, hypocalcemia, myocarditis, sepsis, or infarct (e.g., from an anomalous left coronary artery).

Left-to-right shunt lesions with pulmonary overcirculation, and some left ventricular outflow obstructive lesions, should be appropriately identified based on history, physical examination, and the timing of clinical presentation. Infants with CHF typically present with tachypnea, tachycardia, and diaphoresis. Because the bulk of work performed by infants and small children occurs during feeding, many of these children also have feeding intolerance and failure to thrive. Toddlers and older children usually have tachycardia, tachypnea, fatigue, and exercise intolerance. In older children, peripheral edema and venous distension may be apparent, but they are unusual and are associated with significant right-sided heart failure. Physical examination findings of CHF may include hepatomegaly and a gallop rhythm, with decreased peripheral pulses. On chest x-ray, there is typically cardiac enlargement and increased pulmonary vascular markings, with pulmonary edema. Significant cardiomegaly in the absence of pulmonary vascular congestion should raise suspicion of pericardial effusion.

ED EVALUATION

Structural Congenital Heart Defects

Cardiomyopathy and Myocarditis

Clinical signs of diminished cardiac output and CHF may occur in patients with poor myocardial function due to cardiomyopathy or myocarditis. A cardiomyopathy can be the result of ischemia due to a coronary artery anomaly, a glycogen storage disease, a previous viral infection, muscular dystrophy, an inherited or idiopathic myopathy, or incessant tachyarrhythmia. The degree of symptomatology is usually related to the degree and duration of cardiac dysfunction. The patient with mild dysfunction may present with only mild symptoms of tachypnea and poor feeding (or weakness and fatigue in older patients), whereas the patient with end-stage cardiomyopathy may present in florid CHF and require emergent resuscitation. The child with acute myocarditis may present with severe cardiac dysfunction and an associated tachyarrhythmia (e.g., sinus tachycardia, premature ventricular

contractions, ventricular tachycardia) or bradyarrhythmia (e.g., second- or third-degree heart block).

The classic radiographic findings in these patients include cardiomegaly and, frequently, pulmonary edema. Patients with sustained tachyarrhythmias can have cardiac enlargement as a result of LV failure. Patients with a "dilated," poorly functioning cardiomyopathy may show ECG findings of atrial enlargement, LVH, and occasionally RVH, in addition to, ST-segment or T-wave changes. Children with glycogen storage diseases, such as Pompe disease, may have a short PR interval with very large precordial QRS voltages. Decreased amplitude, manifested as a *low-voltage QRS* (<5 mm total in each frontal lead), suggests myocarditis with decreased contractility or restrictive disease. One also must consider a large pericardial effusion as the cause for low QRS voltage. Patients with an anomalous left coronary arising from the pulmonary artery may have ECG evidence of an ST elevation myocardial infarction (STEMI).

ED MANAGEMENT

In general, the treatment of CHF includes both respiratory and inotropic support. CHF cannot be treated the same in all pediatric patients, due to the wide variety of potential etiologies (7). Infants with cardiogenic shock and septic shock can present similarly, with poor perfusion and metabolic acidosis. However, septic shock requires fluid resuscitation and possibly vasopressors, whereas cardiogenic shock often requires the use of PGE1 infusion.

The approach in the acute care setting should be as follows: (1) to remove any precipitating or aggravating factors (i.e., transfuse for severe anemia, treat dysrhythmias, and possibly restrict fluids), (2) to reduce metabolic demands (reduce fever, sedate agitated patients, consider endotracheal intubation and ventilation), (3) to relieve pulmonary congestion (diuresis, mechanical ventilation with positive end-expiratory pressure, morphine sulfate), and (4) to improve myocardial performance and oxygen delivery (inotropes, afterload reduction, preload reduction, oxygen [which must be used

carefully since it can worsen pulmonary overcirculation], PGE1 [specifically for ductal-dependent left heart obstructive lesions] and correction of metabolic acidosis). In the acute care setting dobutamine and the phosphodiesterase inhibitor milrinone have been successfully used. Dobutamine should be initiated as a continuous infusion at 5 to 10 μg/kg/min. Low-dose dopamine (3 to 6 μg/kg/min) may also be of assistance by promoting diuresis. Milrinone has gained favor in the management of children with myocardial dysfunction; its major advantage is the lack of chronotropic stimulation while assisting with afterload reduction. However, proarrhythmic effects have been reported. Agents such as epinephrine and norepinephrine can be used in the patient with ventricular dysfunction; however, they may aggravate the sympathetic overstimulation of fulminant CHF and also are proarrhythmic.

If the etiology of low cardiac output appears to be poor myocardial function, the initial focus should be on maximizing oxygenation and improving cardiac output through inotropic support, including afterload reduction. In addition, oxygen consumption should be minimized via maintenance of normothermia, normal hemoglobin levels, and preventing or reversing tachycardia.

Unique Complications of Pediatric Congenital Heart Disease

Children with congenital heart disease are at risk for unique complications. Patients with baseline limited pulmonary blood flow are extremely sensitive to acute alterations in pulmonary vascular resistance, and simple respiratory infections (e.g., acute bronchiolitis) are potentially life-threatening in this subset of patients. Patients with defects that limit pulmonary or systemic blood flow require close monitoring for common viral illnesses, such as viral gastroenteritis, as they typically do not tolerate dehydration well.

The Fontan procedure may be performed palliatively in children with complex CHDs. In this staged procedure, systemic venous blood is diverted to the pulmonary arteries without passing through the right ventricle. These patients are at increased risk for pulmonary embolism and for a protein-losing enteropathy that may present with ascites, peripheral edema, and pleural effusions. Patients with shunt-dependent lesions (e.g., pulmonary atresia with a systemic-to-pulmonary shunt) may present with sudden and severe cyanosis and acidosis (and an absence of a continuous shunt murmur on physical examination) owing to thrombotic obstruction of the shunt. Patients with existing right-to-left shunts (either pre- or postoperative) are at risk for stroke, particularly children with polycythemia or chronic cyanosis. These children should have filters on all IV lines to decrease the risk of air emboli. Finally, all children with known cyanotic or complex structural heart disease, or those who have had prosthetic materials inserted, are at increased risk for bacterial endocarditis.

A patient who has had surgery involving the atrium, including the Mustard and Senning operation, is at risk for atrial tachyarrhythmias and sinus node dysfunction. Unlike the typical atrial flutter seen in adults, these patients can manifest atrial tachycardia at a wide range of rates. Ventricular tachycardia is a significant risk of morbidity and mortality in patients with previous ventriculotomy, especially patients with a previous repair of TOF.

CRITICAL INTERVENTIONS

- In addition to congenital heart disease, consider sepsis in a child with poor perfusion and cyanosis.
- Timely prostaglandin infusion for suspected cyanotic ductal-dependent lesions, presenting most commonly within the first week of life. Benefits outweigh the risks even if there is ultimately no cardiac lesion.
- Use supplemental oxygen judiciously in patients where pulmonary vascular resistance must be considered as part of the hemodynamics of an obstructive left-sided lesion.

- Differentiate cardiac from respiratory disease via the hyperoxia test when indicated.

DISPOSITION

Patients with acute problems related to congenital heart disease almost universally require emergent cardiology consultation or critical care admission. If patients are not at a tertiary pediatric center with cardiologic expertise, use of a Neonatal/Pediatric Critical Care Transport Team may be indicated.

Common Pitfalls

- Failure to recognize that cardiogenic shock and septic shock can present similarly, with poor perfusion and metabolic acidosis. Septic shock requires fluid resuscitation and possibly vasopressors, whereas cardiogenic shock in infancy often requires the use of PGE1 infusions.
- Failure to consider a potential cardiac etiology in infants presenting with complaints that include poor feeding, lethargy, dehydration, or septic appearance.
- Delay in institution of prostaglandin infusion.

CHAPTER 269

Appendicitis

Maureen D. McCollough

Appendicitis is the most common surgical emergency in childhood. Despite the decline in mortality since the introduction of antibiotics, over the past 40 years morbidity secondary to delayed diagnosis and perforation has remained unchanged. Perforation rates in children are higher than those in adults and 50% to 70% in preschoolers versus 10% to 20% in adults (1). The clinical progression of symptoms and signs is also more rapid in children. What starts as vague abdominal complaints can quickly progress to ileus, nausea, vomiting, fever, tachycardia, localized pain, and finally peritonitis. The inability of the omentum in young children to wall off localized infections contributes to the development of diffuse peritonitis, which further emphasizes the importance of early intervention (1).

CLINICAL PRESENTATION

The primary cause of appendicitis is obstruction of the appendiceal lumen, caused most commonly by a fecalith (calcified fecal material). Other less common causes of obstruction include inflamed lymphoid tissue, vegetable or fruit seeds, intestinal worms (especially Ascaridae), bacterial infection (with *Yersinia, Salmonella,* or *Shigella*), anomalies of mucous-secreting glands (as in cystic fibrosis), and rarely, retained barium from previous radiographic studies (2).

Luminal obstruction of the appendix causes distention and increased intraluminal pressure, resulting in obstruction of the blood supply. Bacterial invasion occurs and ultimately the ischemic

appendix becomes gangrenous and perforates. Bacteriologic cultures of perforated appendices have revealed polymicrobial organisms, including *Escherichia coli, Bacteroides fragilis,* and enteric streptococci.

Obstruction and distention stimulate appendiceal stretch receptors, relaying pain to the tenth thoracic ganglion, resulting in the perception of periumbilical pain. Bacterial invasion and inflammation then lead to fever, nausea, or vomiting in up to 80% of children. As inflammation extends to surrounding tissues, pain depends on the anatomic location of the appendix. Up to one-third of appendices are located in areas other than the usual location, with the result being that up to 30% of children have pain localized to areas other than the right lower quadrant. A retrocecal location may cause back or flank pain, a pelvic appendix may cause suprapubic pain, and a retroileal location may cause pain referred to the testicle.

If appendicitis is allowed to progress appendiceal rupture will occur. In this case the child is typically ill-appearing, toxic, and dehydrated. Particularly in younger children, the incompletely developed greater omentum is incapable of walling off the inflammatory process, resulting in pain that is more diffuse. The pain may decrease in intensity just after perforation, but typically becomes more severe as peritonitis spreads.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of abdominal pain in children comprises a lengthy list of disorders. The list may divided into five broad categories: (1) intestinal diseases, (2) uterine, tubo-ovarian, or testicular pathology, (3) urinary tract infection or obstruction, (4) systemic illness (respiratory, vasculitic, endocrinologic, and hematologic), and (5) trauma (2).

1. *Intestinal diseases:* Mesenteric adenitis, viral and bacterial enteritis, constipation, Meckel diverticulitis, intussusception, enteric duplication

2. *Uterine, tubo-ovarian, or testicular pathology:* Ovarian or testicular torsion, acute epididymitis, pelvic inflammatory disease, ectopic pregnancy, endometriosis, mittelschmerz
3. *Urinary tract infection or obstruction:* Acute pyelonephritis, cystitis, renal stones
4. *Systemic illness (respiratory vasculitic, endrocrine, hematologic):* Basal pneumonia, Henoch–Schönlein purpura, sickle cell crisis, diabetic ketoacidosis
5. *Trauma:* Accidental or nonaccidental injury

It has been reported that 20% to 40% of children with acute appendicitis are given the wrong diagnosis on the first physician visit (1). The most common erroneous diagnoses, in descending order of frequency, accounting for more than 75% of all missed diagnoses, include acute mesenteric lymphadenitis, no organic pathologic condition, acute pelvic inflammatory disease, ovarian cyst, mittelschmerz, and acute gastroenteritis.

Acute Mesenteric Lymphadenitis

Mesenteric adenitis is often confused with acute appendicitis in children. A careful history in these patients almost invariably reveals the presence of upper respiratory symptoms. Laboratory studies are usually of limited value in differentiation, although a relative lymphocytosis may suggest mesenteric adenitis or a generalized viral syndrome. The abdominal pain is usually more diffuse and less severe than with appendicitis, and generalized lymphadenopathy may be noted on physical examination.

Pelvic Inflammatory Disease

A history of vaginal discharge in a sexually active adolescent can often be elicited. Interviewing adolescents alone, without parental presence, may provide a more informative history regarding sexual activity. Pain is most often bilateral and lower in location than with appendicitis. Physical examination reveals pain with motion of the cervix.

Acute Gastroenteritis

Acute gastroenteritis usually can be differentiated from appendicitis. There is often a history of other ill contacts. These patients have nausea, vomiting, watery diarrhea, and intermittent, crampy abdominal pain. Often, the vomiting precedes the diarrhea by 24 hours. Localizing signs on the abdominal examination are usually absent.

Constipation

Constipation is one of the most significant mimics of appendicitis frequently presenting with abdominal pain localized to the right lower quadrant (see Chapter 230). Often there is a history of hard, pellet-like stools, or decreased stool output. The pain is often colicky and waxes and wanes, but overall, the child appears well between colicky episodes. If the diagnosis is in question or appendicitis is still high on the differential, a mineral oil enema or pediatric Fleet enema may be useful to relieve the pain of constipation.

Meckel Diverticulitis

Preoperative differentiation is unnecessary, because the signs and symptoms of Meckel diverticulitis are similar to those of acute appendicitis, and surgical treatment is indicated for both.

Intussusception

Distinguishing between intussusception and acute appendicitis relies significantly on the age of presentation for each disease. Appendicitis is rare in children younger than 2 years of age, whereas nearly all intussusceptions occur in children younger than age 2. Intussusception typically occurs suddenly in an otherwise healthy infant. The infant “doubles up” with apparent colicky pain, but is usually pain-free between attacks. While a bloody mucoid stool may passed several hours after the onset of pain, this is rare and is an indicator of advanced disease. Physical examination may reveal a sausage-shaped mass in the right lower quadrant.

Occasionally, infants with intussusception present with altered mental status. The diagnosis can be made using ultrasound. In patients between the ages of 1 and 3 years, both of these two entities should carry equal weight in the differential diagnosis until an imaging study such as ultrasound can help clarify the clinical picture. Treatment of intussusception is reduction by barium or air enema (see Chapter 270).

Henoch–Schönlein Purpura

Henoch–Schönlein purpura, a diffuse vasculitis, classically presents with joint pain and swelling and purpura. Abdominal pain may also be a prominent symptom. Rectal examination should be performed for occult blood, and a urinalysis to evaluate for hematuria due to nephritis.

Mittelschmerz

Patients with mittelschmerz are at the midpoint of their menstrual cycle. The pain of mittelschmerz is usually of sudden onset and may be either localized, generally to one of the lower quadrants, or diffuse.

Ovarian or Testicular Torsion

These are often accompanied by anorexia, nausea, and vomiting. The correct diagnosis in boys can always be made by including the genitalia in the physical examination, which usually reveals the subtle findings of asymmetry in gonadal size or position. In girls, ultrasound can be used to make the diagnosis of ovarian torsion more likely if decreased or absent vascular flow is seen unilaterally. And, it should be remembered that normal examination of the ovary, or normal testicular size or position, does not completely rule out the diagnosis of torsion.

Urinary Tract Infection

Urinary bacteria or white blood cells may be present in children with acute appendicitis if the appendix lies near the ureter or bladder. However, with the exception of an elevated specific gravity due to dehydration, the urinalysis is normal in more than 80% of children with acute appendicitis.

ED EVALUATION

The most important steps in the correct diagnosis of appendicitis are eliciting a thorough history and performing a complete physical examination, including examining the external genitalia in boys and performing a pelvic examination in adolescent girls. The diagnostic value of the rectal examination in children is limited; rectal tenderness is present in half of all children with or without appendicitis, and rectal examination should thus be limited to children with rectal complaints.

Examining a young child with abdominal pain can be challenging. Young children are often frightened of doctors and "white coats," but observing the child from the doorway or across the room can be very revealing and yield important clues. Clinicians must not underestimate the value of information gleaned during this early subjective assessment. A young child who is ambulating easily around the room, interested in his or her surroundings, is less a cause of concern than a child who is ill-appearing and lying very quietly. A slight limp when the child walks, hesitation to climb onto the examination table, and inability to stretch the right leg may suggest appendicitis even before the full evaluation. The child usually prefers to lie still in the supine position with the thighs, particularly the right one, drawn up. Vital signs are typically normal, but a child with simple appendicitis may have a mild temperature elevation. Tachycardia may be present if the child is dehydrated, febrile, or in pain.

Abdominal palpation should start away from the painful area. Examination of the abdomen for bowel sounds and tenderness can often frighten young children. Distraction, for example by using a hand puppet or other toy, may help to improve the quality of the

examination. The classic physical finding is point tenderness at McBurney point (3 to 5 cm from the anterior–superior iliac spine on a straight line drawn from that process to the umbilicus) (2). Muscular resistance to palpation of the abdomen parallels the severity of the inflammatory process. Early in the disease, resistance if present consists of voluntary guarding alone. With the progression of peritoneal irritation, muscle spasm increases and becomes involuntary. Bowel sounds are usually normal in early appendicitis, but advanced inflammation, perforation, or both, usually results in an ileus and a quiet abdomen.

Physical signs classically associated with acute appendicitis include Rovsing sign, psoas sign, and obturator sign (3). Rovsing sign tests for peritoneal inflammation by ascertaining the degree of referred right lower quadrant tenderness elicited from palpation of the left lower quadrant. To elicit the psoas sign, the child should lie on the left side and stretch the psoas muscle by slowly extending the right thigh. Alternatively, the child may lie supine and flex the right hip against a hand placed just above the knee. Pain elicited by either maneuver may indicate an irritating focus in proximity to the psoas muscle. Finally, a positive obturator sign occurs when, in a supine patient, passive internal rotation of the thigh (with the hip flexed to 90 degrees) produces right-sided abdominal pain, indicating irritation around the obturator internus muscle. A positive psoas or obturator sign suggests retrocecal or retrocolic inflammation. Although these three signs are often cited as being associated with appendicitis, few studies have evaluated the accuracy of the clinical examination for appendicitis (3).

Given the breadth of the differential diagnosis evaluations must be stratified for age. An abdominal pain evaluation for a 2-year old must include consideration not only of appendicitis, but also of intussusception. On the other hand, in an adolescent female ovarian pathology must be considered far more strongly than intussusception. Selected laboratory tests, including a urinalysis and CBC, may be indicated along with selected imaging studies including ultrasound, CT, or possibly MRI.

The interpretation and integration of findings from the physical examination, laboratory, and imaging studies does not guarantee that every diagnosis will be made, and the literature on the reliability of signs, symptoms, laboratory markers, and imaging in pediatric appendicitis is limited. A systematic review assessing the reliability of common clinical signs for ruling in appendicitis noted that those with the highest positive likelihood ratios were fever, rebound tenderness, and migration of pain to the right lower quadrant. The clinical signs with the highest negative likelihood ratios for ruling out appendicitis were absence of fever and absence of rebound tenderness (4). A history of previous similar pain also seemed to lower the likelihood of appendicitis. Patients with appendicitis, however, do not always present with the "most reliable signs with the highest positive likelihood ratios." Becker et al. specifically studied atypical features in children with confirmed appendicitis to quantify their frequency and investigate which features had the strongest negative predictive value. They noted that 44% of patients presented with six or more atypical features, the most common include (1) lack of fever, (2) absence of Rovsing sign, (3) increased or normal bowel sounds, (4) absence of rebound, (5) lack of pain migration, and (6) lack of abrupt onset of pain. The atypical signs with strongest negative predictive properties based on likelihood ratios included (1) WBC $<10{,}000$ mm^3, (2) an ANC $<7{,}500$ mm^3, (3) absence of guarding, (4) lack of percussive tenderness, and (5) lack of nausea or emesis (5).

A number of clinical decision rules (CDRs) have been developed to help clinicians manage the diagnostic uncertainties of pediatric appendicitis (6). The MANTRALS score by Alvarado dates back to 1986 and was originally developed for adult appendicitis, but has been modified and studied in cohorts of pediatric patients as well. Other scores of note include the Pediatric Appendicitis Score and that by Kharbanda et al. (6). These scores all harness the high-yield indicators of pediatric appendicitis discussed above, including RLQ tenderness, rebound tenderness, leukocytosis, and nausea or emesis. Collectively, however, their performances vary widely and none has proven reliable as a single diagnostic tool that is more accurate than

the clinical intuition of an experienced physician (Mandeville, 2011). Alvarado scores and PAS scores of greater than 7 and 6, respectively, place patients at significantly greater risk for appendicitis but still only achieve sensitivities of 76% and 88%, respectively (Mandeville, 2011).

The application of CDRs in acute appendicitis must therefore fit into a larger picture that includes diagnostic imaging and observation. Ultrasound should be considered a primary modality for the diagnosis of acute appendicitis, in light of the radiation exposure risks associated with CT scans. In children, ultrasound has been reported to have an overall sensitivity and specificity of 90% and 97%, respectively, with an overall accuracy of 96% (7,8). Ultrasound's greatest liability, however, is the variability of its performance across different users and at different centers. Rates of visualization of the appendix, even at experienced pediatric institutions, is only 56%, and at less experienced centers the rate can be as low as 26% (9). Likewise, the sensitivity of ultrasound may vary widely at different centers, ranging from 69% to 86% in experienced centers and from 35% to 52% in institutions where ultrasound is used less frequently or is less available. Specificity, however, appears to be similar across centers, ranging from 96% to 99% (9). Thus, if a normal appendix can be visualized, appendicitis can be ruled out. If the appendix is not visualized, however, or the findings are equivocal, additional evaluation is warranted.

Relative to ultrasound, CT of the abdomen is more sensitive and nearly as specific, with sensitivity and specificity both $>95\%$ and a negative predictive value of 97% (8,10). CT also has been shown to reduce the number of inpatient prediagnosis observation days, operations, and negative laparotomies (11). To balance the superior and more consistent test characteristics of CT against the radiation risk it entails, clinical pathways have been developed that couple CDRs with imaging that stratifies patients and selects imaging modalities according to the likelihood of disease. This maximizes the use of ultrasound as a first-line modality and reserves the use of CT for only the most equivocal cases, which increases its yield. Fleischman et al. published such a pathway that produces a nearly

50% reduction in CT use, from 13% to 7% of cases. Interestingly, their study showed that the accuracy of either a high-risk or a low-risk scoring system was not increased over the clinical impression of an experienced clinician (12).

The newest modality for imaging for appendicitis in young children is focused magnetic resonance imaging (MRI) scanning. Although there are as yet only limited studies (13,14), it appears that MRI provides a sensitivity comparable to that of CTs, but without the radiation exposure. Limitations of MRI include its decreased availability in most medical centers and prolonged scanning time. It should be noted, however, that a less-than-10-minute scanning protocol also appears to be diagnostically successful (15).

Indicated laboratory studies include a complete blood count with differential and urinalysis. Moderate leukocytosis (10,000–18,000 white blood cells [WBC] per mL) with a predominance of polymorphonuclear cells is classically seen but does not necessarily correlate with the severity of the disease (16). A left shift in the differential may precede a total leukocytosis in children. A recent study looked at the use of the WBC and the C-reactive protein (CRP) in the diagnosis of appendicitis in children (17). Used alone, the tests had a sensitivity ranging from 60% to 86%. Used together (either test elevated), there was a sensitivity of 98%, but the 95% CI was as low as 95.3%. It must be noted that a normal WBC or normal CRP does not rule out the diagnosis of appendicitis.

Abdominal radiographs are not particularly helpful, since a fecalith is shown in only 10% to 20% of children with appendicitis. Nonspecific findings on plain abdominal films include isolated distended loops of bowel in the right lower quadrant and obliteration of the psoas shadow. Because lesions that irritate nerves at the T10 to T12 level may simulate the referred pain distribution of appendicitis, a chest film may be required to rule out right lower lobe pneumonia, especially if signs or symptoms of lower respiratory tract disease exist.

There is a higher incidence of perforation in younger children and those with a history of prolonged symptoms. Findings suggestive of

perforation include (1) duration of symptoms >36 hours, (2) temperature >102°F, white blood cell count of >15,000/mL, and (3) physical findings of peritonitis.

The surgical consultant should be contacted as soon as the diagnosis of acute appendicitis is entertained, to avoid the complication of late diagnosis and perforation. Perforated appendicitis has a mortality rate of 5% and a morbidity rate of up to 46% in some series, compared with a mortality rate of 0.1% for nonperforated appendicitis (18).

KEY TESTING

- CBC
- Urinalysis
- Ultrasound
- CT only if indicated
- Observation in the face of equivocal findings

ED MANAGEMENT

Appendicitis is a surgical emergency. All children thought to have an abdominal surgical emergency should be seen by a surgeon as soon as possible. The initial emergency department (ED) management of simple and perforated appendicitis is essentially the same. Once the diagnosis is made, the child must be fluid-resuscitated intravenously and kept NPO.

It was previously believed that the use of analgesic medication such as narcotics in a child with abdominal pain would mask the diagnosis and make the evaluation of the child more difficult. Just as with adults, this has been shown to be untrue (19,20). Multiple studies have found no difference in time to surgical decision, number of perforated appendices, or the rate of negative laparotomies when morphine was compared to placebo in children with diagnosed appendicitis (21).

The same can be said for antiemetics in children. It was believed that children given antiemetics such as prochlorperazine or metoclopramide would be overly sedated and would experience

more dystonic reactions, making the diagnosis more difficult. However, a survey of pediatricians, emergency physicians, and pediatric emergency physicians reveals that the majority use antiemetics in children who are being evaluated for appendicitis (22). The risk of side effects also appears to be lower than first thought (23).

Ondansetron, a serotonin 5-HT3 receptor antagonist, has been shown to be an effective antiemetic in children presenting to EDs with acute gastroenteritis and other conditions, including appendicitis (24,25).

In a child who has been vomiting, obtaining serum electrolyte levels should be considered while intravenous fluid therapy is started. Children who have clinical signs of dehydration should receive 0.9 NaCl or Ringer lactate boluses at 20 mL/kg to maintain urine output at 1 to 2 mL/kg/hr. Once the child is considered fluid-resuscitated, dextrose 5% in 0.45 normal saline and 20 mEq/L KCl at 1.5 times maintenance should be given, as long as the child is not oliguric. If the child is febrile, an antipyretic can be given orally with a small amount of water allowed.

The use of routine antibiotic coverage in children with uncomplicated appendicitis continues to be debated. It appears that short-term perioperative antibiotic prophylaxis in children with acute nonperforated appendicitis may decrease the rate of postoperative infectious complications (26). Absolute indications for extended therapy and a broader spectrum of antibiotic coverage are systemic signs of toxicity, sepsis, suspected perforation, and the presence of underlying conditions predisposing the patient to complications of bacteremia (i.e., infants younger than 6 months of age and children with congenital or acquired cardiac anomalies, sickle cell disease, diabetes mellitus, chronic renal failure, or other states of immune suppression). One commonly used regimen includes ampicillin, gentamicin, and clindamycin. This regimen ensures coverage of aminoglycoside-resistant enterococci, gram-negative bacilli, and anaerobes, respectively. Monotherapy or other antibiotic combinations can be used as long as the same microbial coverage is obtained in the setting of acute uncomplicated disease.

Single-agent treatment with ceftriaxone, piperacillin/tazobactam, or cefoxitin being used with increasing frequency. These appear to be equally efficacious and may result in shortened lengths of stay and reduced hospital charges.

CRITICAL INTERVENTIONS

- Maintain a high index of suspicion for appendicitis in all children with abdominal pain. A retrocecal appendix may cause back or flank pain, a pelvic appendix may cause suprapubic pain, and a retroileal location may cause pain that is referred groin or scrotum.
- Stratify patients and select imaging that balances test performance against the risks of ionizing radiation. After equivocal test results, observation is a valid test.
- Administer 0.9 NaCl or Ringer lactate boluses at 20 mL/kg in children with clinical signs of dehydration to maintain urine output at 1 to 2 mL/kg/hr.
- Obtain a surgical consult as soon as possible to avoid the complications associated with late diagnosis and perforation.

DISPOSITION

All children with appendicitis should be admitted to the hospital for surgical exploration. Laparoscopic appendectomy may be an option is some situations. In certain cases of appendiceal abscess, a surgeon may opt for admission to the hospital for intravenous antibiotics or percutaneous drainage, with an interval appendectomy several weeks later.

If there is doubt about the correct diagnosis but the suspicion for appendicitis is still high, the child should be admitted to the hospital for serial physical examinations. If the suspicion is low but still a consideration, the child may be discharged with clear instructions to return in 6 to 8 hours for a reexamination of the abdomen. If there is any doubt about the ability of the child to return for a revisit, the child should be admitted to the hospital for serial physical examinations.

The child may require transfer to another facility if appropriate surgical staff is unavailable at the initial hospital. This should be done expediently after resuscitation has been started.

Common Pitfalls

- Failure to appreciate atypical presentations of acute appendicitis in children.
- Failure to consider urologic or gynecologic conditions in children.
- Failure to appreciate risk-benefit ratios of different imaging modalities and how they affect decision-making.
- Failure to appreciate the importance of observation as a valid diagnostic test.

CHAPTER 270

Intussusception

Vanessa Tamas and Paul Ishimine

Intussusception is an invagination of any segment of the intestine. This occurs when the proximal portion of the intestine invaginates into the distal, adjacent part. The majority of pediatric intussusceptions are ileocolic in origin (1).

Intussusception is the most common cause of intestinal obstruction in children, occurring with a frequency of 56 per 100,000 children per year (2) Typically, intussusception occurs in children less than 2 years of age, with most episodes occurring between the fifth and the ninth month. However, intussusceptions have been reported throughout the age spectrum, from the neonatal period through adulthood (3).

Idiopathic intussusceptions account for more than 90% of cases (4). Viral illness, immunization against rotavirus, and pharmaceuticals that include promotility medications and oral antibiotic agents have been implicated in these patients (5). In up to 10% of cases, a cause for intussusception is found, usually a well-defined pathologic lead point. A lead point is found with some frequency after 4 years of age, and is found consistently after 14 years of age (6). Conditions associated with intussusception include lymphoma, Henoch–Schonlein purpura, hemolytic-uremic syndrome, Meckel diverticulum, familial polyposis, Peutz–Jeghers syndrome, mesenteric adenopathy, and inverted appendiceal stumps. The possibility of an underlying lead point should be considered in patients who present with recurrent episodes, those out of the typical age range, and those with small bowel–small bowel intussusception. Irrespective of cause, early diagnosis is

essential; the duration of intussusception before treatment bears a close relationship to its morbidity and mortality.

CLINICAL PRESENTATION

The cardinal symptoms of intussusception are abdominal pain, vomiting, and rectal bleeding (1). In a typical case, there is a sudden onset of severe abdominal pain that may last several minutes. After an asymptomatic interval, repeated paroxysms will cause the child to cry out again. The child may be impossible to console or may seem comfortable only in a knee-chest position in the arms of a caregiver. Vomiting may occur either with the initial painful episode or soon after. Concurrent with vomiting, the child usually has one or more bowel movements, which may vary from thin liquid to formed stools. Within 12 to 24 hours, mucus, blood, or both may be passed per rectum (7).

Only 25% to 65% of patients present with the classic triad of paroxysmal pain, vomiting, and rectal bleeding; most patients develop only colicky abdominal pain and vomiting. (2,4,7). Nonbilious vomiting may become bilious as bowel obstruction progresses. Rectal bleeding is a less constant historic feature and may be found in as few as 40% of patients (8). Frank blood, or blood-streaked stools, may be present in a few hours of the first painful episode. “Currant jelly” stools account for a minority of bloody stools and are typically observed only after prolonged illness (9).

Recognition of the stereotypic history facilitates the diagnosis. However, less-than-classic presentations are frequent and contribute to diagnostic uncertainty and increased morbidity. Among the main factors that contribute to misdiagnosis are altered mental status and listlessness. Valuable time may pass during a well-considered evaluation for altered mental status that is not focused on an abdominal etiology. Altered mental status with intussusception is frequently associated with a prolonged course of illness (10). Furthermore intussusception may be considered late or not at all in patients presenting outside the conventional window of the first 2

years of life. A painless event may occur in 15% of cases (11). Occasionally no blood passes per rectum. The rectal examination early in the course may show show that is normal in appearance, and guaiac testing may be negative.

The vital signs and physical appearance of an affected child may be variable. Most children will be alert and hydrated. Those with advanced disease complicated by either fluid or electrolyte imbalance, or blood loss, may appear less responsive. Not uncommonly, a child with a very brief history of enteric manifestations may be obtunded at presentation. It is speculated the decreased level of consciousness observed in some patients is due to the release of natural endorphins from the intussusceptum.

On inspection, the abdomen may appear scaphoid and the right lower quadrant may seem empty. A sausage-shaped mass, sometimes ill-defined, can be palpated occasionally in the right upper quadrant. Rectal examination may reveal blood, ranging from occult blood noted on guaiac testing to frankly bloody stools. Rarely, rectal prolapse may be noted.

DIFFERENTIAL DIAGNOSIS

Because the signs and symptoms of intussusception overlap with many other clinical diagnoses the differential diagnosis is broad. Conditions that are commonly confused with intussusception include gastroenteritis and constipation. Other entities that should be considered, especially in infants, include malrotation with volvulus, incarcerated hernia, necrotizing enterocolitis, allergic or infectious colitis, and gastroesophageal reflux.

Gastroesophageal reflux, the most common cause of emesis in infants can be misinterpreted as intussusception when it is accompanied by abdominal pain. Bloody stools in infants can also be indicative of underlying allergic colitis; however, patients with allergic colitis generally appear well without vomiting or abdominal pain. Appendicitis can present similarly, with abdominal pain and vomiting and is one of the most challenging entities to differentiate from intussusception.

In patients who present primarily with lethargy, the differential diagnosis is similarly broad and complex. Electrolyte abnormalities, notably hypoglycemia and hyperglycemia should be ruled out. Primary neurologic diseases such as intracranial masses, hemorrhage, ingestion, or seizures need to be considered.

If a right upper quadrant mass is present, other causes of abdominal mass in children in this age should be considered. Wilms tumor is generally characterized as painless and is not usually associated with vomiting. The presence of hematuria would differentiate this from intussusception. Hepatoblastoma can be felt originating from the liver. In patients with neuroblastoma, there can be a history of weight loss, flushing, irritability, diarrhea, and possible electrolyte abnormalities such as acidosis and hypokalemia. If neuroblastoma invades or encroaches upon the spinal cord, lower extremity hyperreflexia and flaccidity may be present.

ED EVALUATION

There are no laboratory tests that can confirm the diagnosis of intussusception, but testing can assist with risk stratification of patients in whom this diagnosis is considered. A stool examination for occult blood has a high benefit-to-cost ratio. A negative guaiac should not be used to exclude the diagnosis, yet a positive stool guaiac should reduce the threshold for further evaluation and management decisions. Other laboratory tests are generally used to exclude other conditions that may have similar presentations. Tests that may help narrow the differential diagnosis include a complete blood count, C-reactive protein, glucose, electrolyte panel, liver function testing, urine analysis, and stool culture. In an ill-appearing child in whom there is concern for underlying peritonitis, sepsis, or perforation, an arterial or venous blood gas, lactate level, and coagulation studies may be helpful. Urine drug screen and computed tomography scan should be considered in patients who have painless intussusception presenting as profound lethargy. The child who appears septic should undergo blood, urine, and cerebrospinal fluid testing.

When intussusception is considered, abdominal radiographs can be utilized to help with risk stratification. Most centers perform two-view radiographs, including supine and left lateral decubitus, but the addition of a third prone view has been argued to further assist in diagnosis (12). Common findings on radiographs that are consistent with intussusception include the presence of a soft tissue mass (typically in the right upper quadrant, often with loss of the visible liver margin), a target sign (concentric radiolucent circles overlying the right kidney), a crescent sign (the cap of the intussusceptum seen within the lumen of the intussuscipiens), paucity of air within the ascending colon or right lower quadrant, and evidence of small bowel obstruction. However, radiographs may be normal, especially early in the course of the disease, or equivocal (13,14). Interobserver reliability among radiologists remains imperfect as well. Thus, negative plain abdominal x-rays do not rule out intussusception and should be followed by ultrasound if intussusception is suspected clinically. The presence of free air precludes reduction by enema.

Children in whom the history and physical examination are highly suggestive of intussusception, should proceed directly to an abdominal ultrasound. Ultrasound is superior to abdominal radiographs, with a sensitivity and specificity that both approach 100%. Ultrasound has been successfully performed by both radiologists and pediatric emergency physicians (15). Ultrasound findings consistent with intussusception include a “target sign” on transverse scan, as well as a “pseudokidney” or “sandwich” sign on longitudinal scan. Ultrasound is the initial diagnostic study of choice for most patients, as it provides a rapid diagnosis without exposure to radiation and allows for evaluation of possible pathologic lead points or alternative diagnoses. Studies have shown that emergency physicians, with limited training, can accurately diagnose idiopathic ileocolic intussusception utilizing bedside ultrasound. If ultrasound is not available, or if the ultrasound results are equivocal, either a barium or contrast enema can be performed, since it is both diagnostic and therapeutic. Abdominal computed tomography scans can accurately detect intussusception, but because of the significant

associated radiation exposure involved, ultrasound is preferred when the suspicion for intussusception is high.

KEY TESTING

- Abdominal ultrasound
- Air or contrast enema

ED MANAGEMENT

Most patients who have suspected intussusception require the placement of an intravenous line. These patients should undergo fluid resuscitation as well as correction of any underlying electrolyte imbalances. Although not universally performed, pending imaging procedures, a nasogastric tube should be considered. All patients should be made NPO (i.e., nothing by mouth).

Once intussusception has been confirmed, the patient should be referred for reduction, either via pneumatic or barium enema. Successful reduction rates are variable, but reported to be as high as 80% to 95% (16). Pneumatic enemas are currently favored over barium enemas given the risk of chemical peritonitis if perforation were to occur. Perforation is more likely to occur in patients who are diagnosed later, presumably owing to the higher degree of bowel edema and friability. Surgical reduction is indicated in patients in whom the diagnosis has been delayed or in those in whom reduction cannot be completed by enema. Patients who present with recurrent intussusception should also be considered for surgical reduction, to allow for exploration for a pathologic lead point (17). Surgical options for reduction are at the discretion of the surgeon and include both open and laparoscopic techniques. In patients in whom sepsis, peritonitis, or perforation is suspected, immediate fluid resuscitation, antibiotics, and surgical consultation should be obtained immediately. Antibiotics are not routinely recommended for patients in whom perforation is not suspected.

CRITICAL INTERVENTIONS

- There should be a low threshold for ordering an ultrasound to evaluate for intussusception.
- Children with apparent intussusception require hemodynamic stabilization before undergoing imaging.
- After stabilization, further treatment of intussusception is directed at reduction of the intussusception, most commonly by air or contrast enema.
- Appreciating the importance of timely reduction after the diagnosis is made—"time is bowel."

DISPOSITION

Well-appearing patients who have undergone successful contrast enema reduction can be discharged after a period of observation and successfully tolerating oral intake (18,19). If the patient continues to appear ill or dehydrated admission is warranted for further resuscitation. If the enema reduction was particularly difficult, indicating delayed diagnosis and more severe ischemia, observation should be considered. Parents should be counseled that in approximately 10% of children (20), intussusception recurs, the majority of which occur in the first 24 hours. Parents should be advised to return to the ED if pain or vomiting recurs.

Common Pitfalls

- Obstacles to accurate diagnosis include failure to recognize the typical history, failure to perform a rectal examination, reluctance to accept the diagnosis in a well-appearing child with a prolonged history, and failure to consider the disease in older children.
- Marked variation from the classic picture may lead to misdiagnosis. The absence of pain, lack of a mass, presence of bright red rectal bleeding, or altered mental status should not dissuade one from considering the diagnosis.
- A normal plain abdominal radiograph in a suspected case of intussusception should not deter performance of further imaging studies such as ultrasound.

ACKNOWLEDGMENT

The authors of this chapter wish to credit the previous edition author, Dr. Adam Singer for is past contributions.

CHAPTER 271

Malrotation and Midgut Volvulus

Maybelle Kou

Intestinal malrotation with midgut volvulus is a form of torsion in which the small intestine wraps around the superior mesenteric artery (SMA). It is a diagnostically challenging condition particularly in infants causing significant morbidity and mortality if not diagnosed and corrected in a timely fashion (1). This congenital defect may not be symptomatic unless coupled with a midgut volvulus which leads to potentially catastrophic bowel ischemia. Bilious vomiting is the hallmark feature of malrotation with midgut volvulus, and is a complaint that must be evaluated thoroughly in all cases.

Intestinal malrotation is reported to occur in 1/200 to 1/500 live births, although *symptomatic* malrotation may occur in only 1/5000 live births (2–4), most commonly in the first few months or the first year of life (3). Despite the preponderance of early presentations, malrotation may remain asymptomatic for years, with a likely higher prevalence than reports suggest. Cases of malrotation with midgut volvulus have been described in the adult literature, and should be considered in the differential diagnosis of an adolescent or adult presenting with UGI obstruction or undifferentiated intermittent abdominal pain (1).

EMBRYOLOGIC AND ANATOMIC CONSIDERATIONS

Malrotation results from the abnormal embryologic rotation positioning and anchoring of the intestinal midgut with respect to the SMA.

Critical anatomic structures associated with intestinal malrotation are the duodenojejunal and cecocolic midgut; these are portions of the intestine proximal and distal to the SMA. During the 5th week of embryologic development, after extrusion and rapid lengthening through the abdominal wall, the intestine makes two distinct 270-degree turns in a counterclockwise direction upon return into the peritoneal space by the 12th week (3,4). Proper embryologic rotation allows fixation of the proximal midgut (duodenum) in the left upper quadrant at the ligament of Treitz, the junction at which the duodenum transitions from the retroperitoneum to become the jejunum (duodenal–jejunal junction [DJJ]). The distal midgut (cecum) comes to lie in the right iliac fossa. The intermediate intestine lies anteriorly, encased in a "fan" of omentum." In the most common form of malrotation, this counterclockwise rotation is incomplete, the position of the proximal midgut anchoring posteriorly relative to the SMA and the distal portion anchoring anteriorly with additional colonic attachments to the right retroperitoneum, known as Ladd bands. *Midgut volvulus occurs with the twisting of the midgut about a narrow pedicle in the axis of the SMA placing bowel supplied by the SMA at risk for ischemia.* There are a number of anatomic variants that complicate the diagnosis of malrotation. Ladd bands, for example may compress the duodenum and create intermittent symptoms similar to but not necessarily midgut volvulus (3).

CLINICAL PRESENTATION

The clinical presentation of children with intestinal malrotation is variable and dependent on the presence or absence of volvulus which can be notoriously episodic. Symptoms may or may not include bilious vomiting, intermittent abdominal pain and distension (2). While most cases of malrotation with midgut volvulus will present in small children, the diagnosis must still be

entertained in older children presenting with UGI obstruction whose early courses may have been more indolent or asymptomatic.

Neonatal Presentations

Vomiting in infancy is a common emergency department (ED) chief complaint, however, *an infant with bile-stained vomit has malrotation with midgut volvulus until proven otherwise.* The range of presentations can be widely variable. Infants with bilious emesis alone may have an unremarkable initial examination and appear well. The least challenging and most obvious presentation in the neonatal age group is of bilious vomiting, and abdominal distension. Bloody diarrhea has been described and infants may present with crying spells or symptoms of dehydration including lethargy and fatigue. Infants who have progressed to bowel ischemia and infarction may appear to be in shock with the appearance of sepsis.

Infant and Childhood Presentations

Older infants and children with intermittent volvulus may present with intermittent pain with or without vomiting. While bilious vomiting is an ominous sign and may suggest UGI obstruction and/or volvulus, it is not always present. Malrotation should be suspected in a child with chronic intermittent idiopathic abdominal pain, chronic malabsorption and/or diarrhea, however, in a well-appearing child with no acute impending intestinal catastrophe a less emergent work-up can be arranged.

DIFFERENTIAL DIAGNOSIS

In addition to conditions described above, the differential diagnosis of a neonate with bilious vomiting and abdominal distension should also include NEC, duodenal webs, strictures, intestinal ileus, and Hirschsprung disease. Infants and children with intussusception can also present with symptoms of UGI obstruction, vomiting, and shock due to intestinal ischemia that may be impossible to distinguish clinically. Incarcerated hernias may also paint a picture of bowel obstruction. The diagnosis must also be entertained in infants with

failure to thrive, such as those that exhibit poor feeding or persistent intermittent nonbilious vomiting. This may be mistaken for conditions such as milk intolerance, pyloric stenosis or GERD. Infants with "heterotaxy" (congenital cardiac defects) may also be at high risk for intestinal malrotation due to visceral anatomic abnormalities. Finally, there is a clear association between children with intestinal malrotation and other congenital anomalies (3).

ED EVALUATION

The evaluation of infants or children with bilious vomiting and the suspicion of malrotation with midgut volvulus should include rapid assessment for dehydration and shock. Those presenting in shock should have prompt initiation of intravenous fluid resuscitation and gastrointestinal decompression, including airway protection and nasogastric tube placement. A detailed feeding history should be performed on any infant with vomiting to elicit relationship to feeding, weight gain, history of prematurity, stooling patterns, and concurrent illness. Physical examination should be performed carefully, noting presence of abdominal bowel sounds, peritoneal signs, and other anatomic considerations such as hernias and imperforate anus.

The ill-appearing child with evidence of ongoing symptoms and dehydration, may exhibit electrolyte disturbances, however in well-appearing children, blood work may be unrevealing. In ill-appearing children laboratory work is unlikely to compliment medical decision making and should not delay radiographic studies or surgical consultation. The literature does not describe utility of inflammatory markers for this condition, although serum lactates have long been used in the diagnosis of intestinal ischemia in adults their utility in children is not proven and not currently recommended. In short there is no definitive laboratory study for the diagnosis of malrotation with midgut volvulus; diagnosis relies on timely radiographic evaluation.

UGI Series: The current gold standard test for diagnosis of malrotation and midgut volvulus is the contrast UGI series, the

purpose of which is to document the position of the DJJ and cecum and attempt to measure the mesenteric base (5). The radiology literature stresses the need for meticulous technique in acquiring these images, with a false-positive rate of up to 15% of patients (3) and reports of false-negatives (6). It is important that ED physicians understand the limitations of available testing (6,7). Most institutions follow local protocols with a combination of pulsed and still fluoroscopic images of the passage of orally administered contrast. This is followed with a delayed (5 minutes) AP view, the small bowel follow through. A confirmatory study may reveal a "double bubble" that is caused by Ladd bands compressing the duodenum, or the downward "corkscrew" appearance of the obstructed distal duodenum and proximal jejunum (Fig. 271.2). A shortened mesenteric base is associated with a higher risk of volvulus. In a retrospective study of 163 children the sensitivity of a UGI to diagnose malrotation was reported at one institution to be as high as 96%, and to detect volvulus 79% (7). This study stresses the importance of a true lateral view to document the position of the duodenum, and of a small bowel follow through to determine the position of the cecum in indeterminate cases. The overfilled stomach can also displace bowel, so a baby should not be overfed contrast (3). Delayed films in stable patients may also be helpful in diagnosis of in determinant cases.

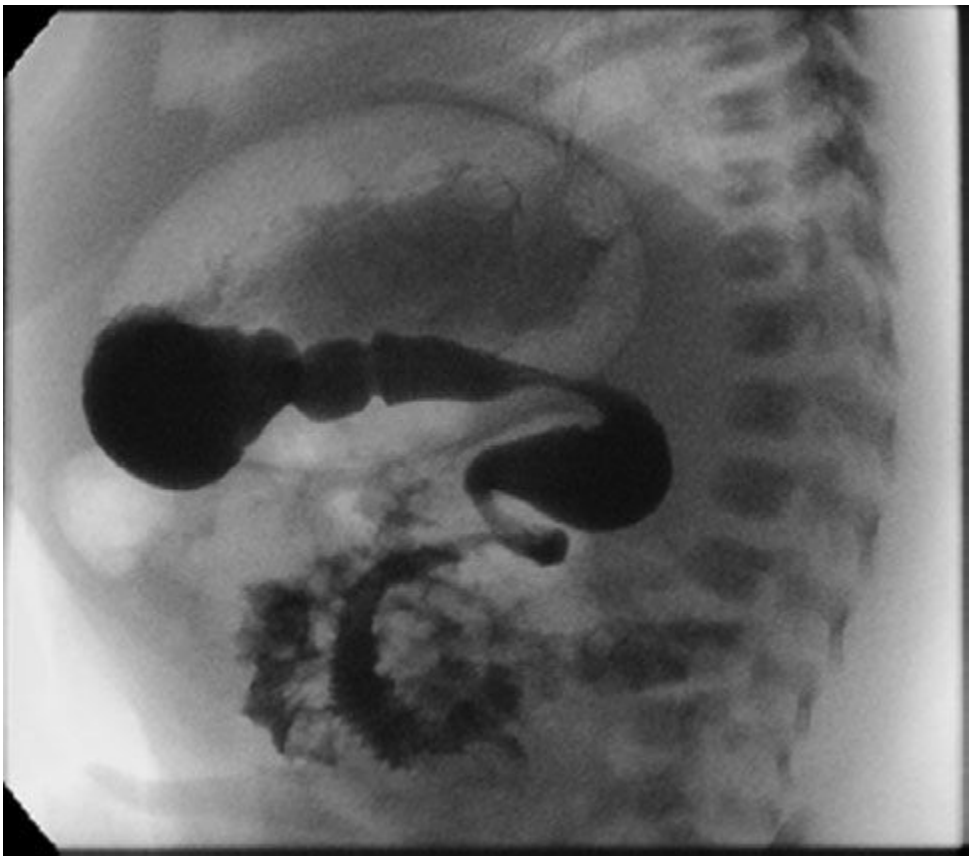

FIGURE 271.2 This image demonstrates the "corkscrew" appearance of a midgut volvulus. (Image courtesy of Dr. John Lee.)

Ultrasound: Although ultrasound has become increasingly popular in conjunction with the UGI series for the diagnosis of malrotation and volvulus, studies in the literature are limited with no prospective comparisons of UGI series to US. The purpose of ultrasound is to document the relationship of the superior mesenteric vein and artery (SMV/SMA) orientation, which may not always be visualized, and to detect the "whirlpool" sign seen in volvulus that suggests but is not always present (case reports of the whirlpool sign *without* volvulus have been published). Sensitivities of US alone are insufficient for its use without UGI, however it may be helpful in cases where UGI is not confirmative. Limitations of US notwithstanding, the study must be performed accurately, is operator dependent and may not be available at all institutions (8).

Plain radiography: A paucity of bowel gas may be suggestive of malrotation but also of many other things as well. While not sensitive for malrotation, plain radiography may be helpful to rule out other causes of abdominal distension, including NEC, megacolon, or free air (6,7) (Fig. 271.3) demonstrate a double bubble.

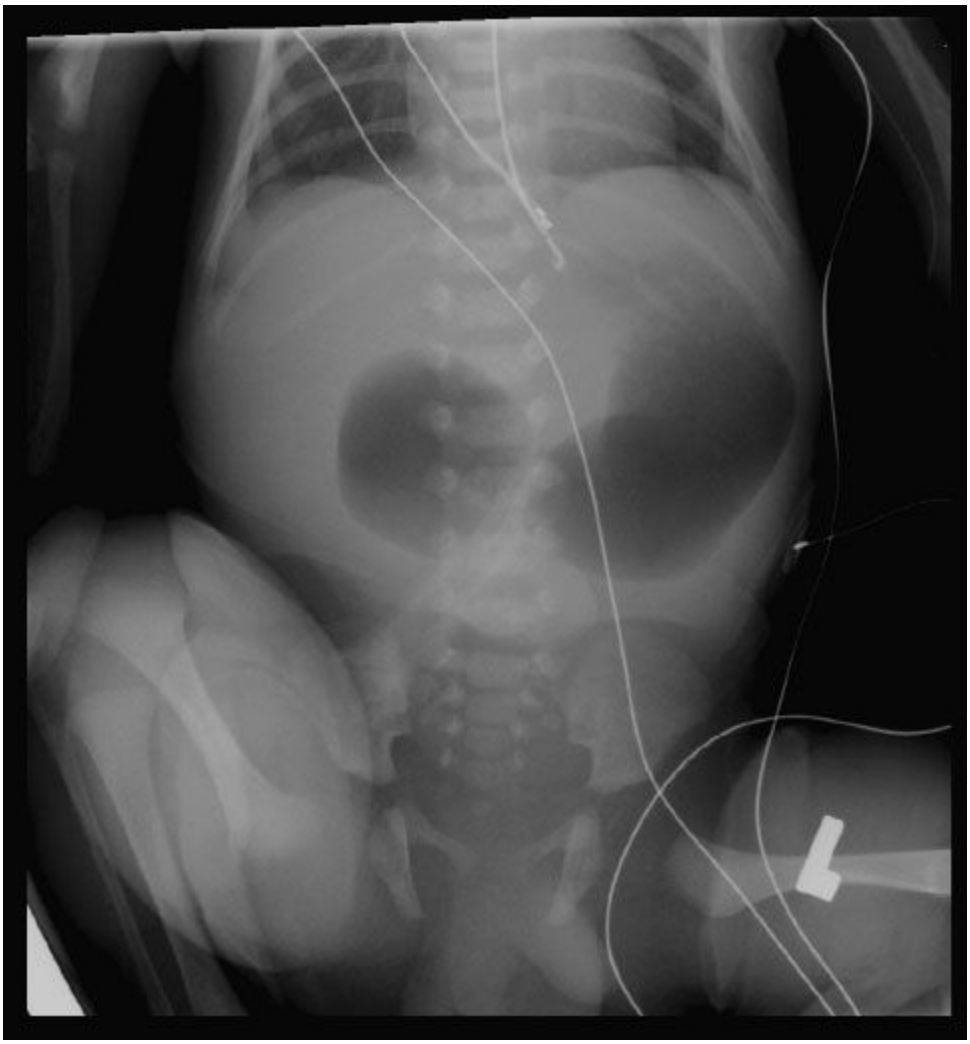

FIGURE 271.3 *Double-bubble sign: This image demonstrates gastric distension and paucity of air in the distal bowel, suggestive of midgut volvulus. (Image courtesy of Dr. John Lee.)

Computed tomography and barium enema are not currently considered first-line tests in the diagnosis of malrotation in children, however, may be employed if gold standard tests are unsuccessful in

making a diagnosis in a stable patient in whom the suspicion is high.

KEY TESTING

- UGI must be performed on any infant less than a year old with a history of bilious vomiting. This must demonstrate passage of contrast beyond the ligament of Treitz.
- Ultrasound may be used in conjunction with UGI.
- Abdominal x-ray does not replace the UGI.
- CBC, electrolytes, type, and cross.

ED MANAGEMENT

If the suspicion for malrotation is high enough based on clinical presentation, and primary assessment and fluid resuscitation have been initiated, further management depends largely on institutional capability and protocols. **If diagnostic tests are not available, the child should be transferred to the closest full service pediatric facility.** Temporizing measures must include intravenous fluid resuscitation, via IO if necessary, and nasogastric decompression. Antibiotics should be administered urgently in patients with peritoneal signs or evidence of infection. Antiemetics, such as ondansetron, may quell symptoms of nausea. Analgesia should be considered. Time is of the essence in the treatment of this entity.

CRITICAL INTERVENTIONS

- Low threshold for ordering UGI in infants with a history of bilious vomiting
- Recognition of volvulus, dehydration, impending shock
- IV fluid resuscitation via IO if necessary
- NG decompression/management of SBO
- IV antibiotics if suspicion of peritonitis
- Urgent or emergent radiologic evaluation
- Transfer to appropriate facility if tests and treatment are not immediately available

DISPOSITION

Intestinal malrotation and volvulus is a time-sensitive surgical emergency requiring immediate definitive surgical intervention. The most commonly performed procedure is named for William Ladd who pioneered the treatment (4). The Ladd procedure involves operative detorsion of the volvulus and division of Ladd bands to mobilize the cecum. Once the bowel is detorsed, and blood supply restored, the intestines are repositioned. In septic-appearing patients the discovery of frankly infarcted bowel is undesirable, and must be sacrificed if reperfusion is unsuccessful. Recurrent volvulus, although rare, has been described both immediately postsurgery and years later. A case report of successful use of thrombolytics in two neonates with volvulus and mesenteric thrombi has recently been described (9). Well-appearing, asymptomatic patients with incidental findings of malrotation can be managed with surgical consultation and follow-up.

Common Pitfalls

- Failure to consider malrotation in patients who do not present with bilious vomiting.
- Failure to consider malrotation if there is no vomiting or only intermittent volvulus.
- Failure to consider malrotation in any neonate presenting with bilious or intractable vomiting or reflux symptoms.
- Failure to consider malrotation in an infant or child with a grossly distended abdomen and symptoms of UGI obstruction.

CHAPTER 272 Pyloric Stenosis

Ronald A. Furnival and Marissa A. Hendrickson

Hypertrophic pyloric stenosis is the most common surgical etiology of nonbilious vomiting in young infants presenting to the emergency department (ED) and the most common indication for abdominal surgery before 6 months of age (1). Pyloric stenosis occurs in 2 to 5 of every 1,000 infants, affecting four to five males for every female. The etiology of pyloric stenosis appears to be multifactorial, with a number of genetic, biochemical, and environmental associations (2). Erythromycin treatment during the first 2 weeks of life has been associated with a moderately increased risk for developing pyloric stenosis (2,3). Regardless of the underlying cause, pathologic gastric outlet obstruction results from hypertrophy of the pyloric muscle, leading to vomiting, dehydration, poor weight gain, and eventual hypochloremic metabolic alkalosis as the "classic" presentation.

CLINICAL PRESENTATION

The typical infant with pyloric stenosis has symptoms beginning on average at 3 weeks of age, with gradually worsening nonbilious vomiting. Pyloric stenosis is relatively rare among newborns younger than 1 week of age or infants older than 3 to 4 months of age; premature infants may present according to their corrected age (4). The progressive vomiting of pyloric stenosis is often characterized as "projectile" in nature, although it is not necessarily a key consideration in diagnosis and can be difficult to pinpoint historically (5). The infant with pyloric stenosis may also have a history of blood-streaked or "coffee-grounds" emesis from gastritis,

weight loss or poor weight gain relative to the birth weight, and physiologic jaundice (1).

As infants with pyloric stenosis present at an earlier age, often without significant complications, their physical examination findings have become correspondingly more subtle. These infants often appear continuously hungry, even after vomiting an attempted feed. With more advanced cases, the infant may appear thin-limbed and cachectic, with reduced subcutaneous fat stores, weight loss, and evidence of dehydration in up to 30% of cases (6). Visible peristaltic waves may be noted in the epigastrium (5). There has been a decrease in the proportion of infants presenting with the classic findings of hypochloremic alkalosis, weight loss, and a palpable pyloric muscle mass or "olive" in the right epigastrium (7). The use of a sucrose-dipped pacifier, ventral decubitus positioning or flexed-hip positioning, nasogastric (NG) or orogastric tube placement for gastric emptying, and a very gradual approach may improve the likelihood of successful palpation of the olive (5). However, with the advent of modern imaging the frequency with which a palpable olive is documented has decreased from as high as 99% of cases in the 1970s to 13% currently (7).

DIFFERENTIAL DIAGNOSIS

The most common cause of nonbilious vomiting in the otherwise healthy infant is gastroesophageal reflux. The infant with reflux may have a history of overfeeding, positional variation in symptoms, or respiratory complications in the more advanced cases (8). Other common medical conditions presenting with nonbilious vomiting include viral gastroenteritis or an occult urinary tract infection, although both usually would have a history of shorter duration, with fever or other associated symptoms. Central nervous system disorders (hydrocephalus, intracranial hemorrhage, meningitis) may present with vomiting but seldom without associated neurologic findings in a healthy-appearing infant. Less common medical causes of nonbilious vomiting during infancy include congenital adrenal hyperplasia, inborn errors of metabolism, or renal insufficiency,

which may present with characteristic electrolyte abnormalities (i.e., hyponatremia and hyperkalemia with the salt-wasting form of adrenal hyperplasia) or specific diagnostic laboratory findings (9).

Though pyloric stenosis is the most common surgical consideration associated with nonbilious vomiting in early infancy, other surgical conditions (intestinal malrotation with volvulus, intussusception, Hirschsprung disease, tracheoesophageal fistulas, esophageal or duodenal webs, duodenal atresia or stenosis, appendicitis, incarcerated hernia) must also be considered. Most infants with pyloric stenosis are initially well and *gradually* develop progressive vomiting over time. Congenital abnormalities of the upper gastrointestinal tract generally present early in the newborn period, without a progressive history of feeding difficulty. The infant with evidence of abdominal pain, abdominal distention, or bilious (either yellow- or green-stained) emesis must be considered to have an emergent surgical condition until proven otherwise. Immediate surgical consultation should be arranged, and imaging studies should be performed as necessary for diagnosis (10).

ED EVALUATION

If the infant's history and physical examination raise the possibility of pyloric stenosis, carefully attempt to palpate the olive for diagnosis. If the olive can be felt, no further diagnostic work up is required, and the surgeon can be notified. An imaging evaluation is appropriate if the abdominal examination does not reveal the diagnosis.

Abdominal imaging is performed in 70% to 90% of infants with pyloric stenosis, including those with a palpable olive. Though an increased use of imaging is credited with the earlier diagnosis and improved clinical condition of today's infants with pyloric stenosis, imaging is not necessary for those with a clear diagnostic examination. Upper gastrointestinal contrast imaging has been used, but ultrasound has increasingly become the modality of choice (11). With growing experience in ultrasonography among surgeons and emergency physicians, bedside ultrasound is emerging as a

possibility (12–14). In patients with pyloric stenosis, ultrasound shows a thickened and elongated pylorus, with a thickness of 3 mm or greater, and pyloric length of 15 mm or longer, having 100% sensitivity and 97% to 99% specificity for the diagnosis (15).

KEY TESTING

- Infants suspected of having pyloric stenosis should be evaluated with focused abdominal ultrasound to establish diagnosis.
- Assess serum glucose and electrolytes for hypoglycemia, metabolic alkalosis, hyperchloremia, and hypokalemia.

ED MANAGEMENT

Once the diagnosis of pyloric stenosis is clear, intravenous (IV) access should be obtained, and the infant should remain NPO. NG tube placement for gastric decompression is controversial as it may increase complications, so it is generally not recommended (16). Blood should be obtained for the measurement of serum glucose and electrolytes. With earlier recognition of the condition electrolyte abnormalities, ranging from metabolic acidosis early on, to the classic hypochloremic metabolic alkalosis with more advanced illness, are uncommon (<15% of cases) (7). Infants presenting with elevated serum bicarbonate (>25 mEq/L) and severe hypochloremia (<99 mEq/L) generally have had a longer duration of vomiting, with more severe dehydration and greater weight loss, and as a result may have longer hospital stays (5,7).

The primary goals of preoperative care are IV fluid resuscitation and correction of any electrolyte and acid–base imbalances. Preoperative fluid resuscitation should consist of one or two initial 20 mL/kg IV boluses of normal saline, followed by 5% dextrose and one-half normal saline at 1.5 times the infant's maintenance rate. If the serum potassium is not elevated, 20 mEq/L of KCl should be added to the IV infusion. Complete fluid resuscitation with correction of alkalosis prior to surgery decreases the risk of postoperative apnea (5).

CRITICAL INTERVENTIONS

- The dehydrated infant with suspected pyloric stenosis should receive 20 mL/kg IV normal saline boluses and have a serum glucose and electrolyte panel sent to the lab while awaiting surgical consultation or imaging studies.
- Adjust the IV fluid infusion to 5% dextrose and one-half normal saline at 1.5 × the maintenance rate after the initial boluses. Include 20 mEq/L KCl if the serum potassium is not elevated.
- Keep the infant NPO.

DISPOSITION

The infant with diagnosed pyloric stenosis must be hospitalized for fluid resuscitation and surgical intervention. The Ramstedt extramucosal pyloromyotomy remains the standard approach, with excellent cosmetic and functional outcomes, minimal morbidity, and very low mortality (<0.5%) (17–22). Though the open procedure has had a record of remarkable success and longevity, laparoscopic pyloromyotomy is gaining favor. A number of recent studies have shown small improvements in some outcomes with the laparoscopic approach, including shorter stays, improved cosmesis, and better cost-effectiveness (19,22–26). Excellent outcomes for either procedure appear to be volume dependent for both the surgeon and the institution, with fewer complications noted for those with larger numbers of procedures (17,20,21) and in children's hospitals compared to general hospitals (27). Early postoperative feeding protocols have reduced the total hospital length of stay for the average infant with pyloric stenosis to 48 hours, with few complications. Post-pyloromyotomy vomiting is common, with coexisting gastroesophageal reflux present in 10% to 15% of affected infants. This vomiting usually resolves within 1 to 2 weeks after surgery; persistent vomiting may represent the very rare failed pyloromyotomy. Nonsurgical medical therapy for pyloric stenosis with IV atropine has been studied primarily in Europe and Japan, but it requires a significantly longer hospital stay than pylorotomy,

has an unacceptably high failure rate, and is rarely used in North America (28).

Common Pitfalls

- Assuming that bilious vomiting in the infant <2 months of age is pyloric stenosis. Bilious emesis mandates an immediate UGI for possible malrotation and volvulus, as well as prompt surgical consultation.
- Inadequate IV fluid resuscitation in the infant with hypochloremic metabolic alkalosis.

CHAPTER 273
Foreign Bodies

Tim Young and Lance Brown

The emergency department (ED) management of foreign bodies can be simple and rewarding. There are three basic elements of management: (1) attempted removal, (2) reassurance, and (3) consultation. The plan will depend on the body cavity, the foreign body, and the clinical presentation. This chapter discusses foreign bodies of the ear, nose, airway, and gastrointestinal tract. Management of pediatric vaginal foreign bodies is discussed in Chapter 287.

EAR FOREIGN BODIES

CLINICAL PRESENTATION

Children of all ages have been described with foreign bodies in the ear canal (median age 6 years) (1,2). Presenting complaints may include pain, discomfort, decreased hearing, and bleeding (1). Ear foreign bodies include insects, paper, beads, seeds, eraser tips, earring parts, toy parts, and disk or button batteries (1–4).

DIFFERENTIAL DIAGNOSIS

It is usually easy to identify foreign bodies in the ear canal. Impacted wax and rare ear canal masses may be mistaken for foreign bodies. Chemicals released from disk or button batteries can cause an intense localized inflammation that can mimic otitis externa (3).

ED EVALUATION AND MANAGEMENT

The ED evaluation of a suspected ear foreign body is almost always straightforward and involves visual inspection of the ear canal with an otoscope. If a button battery is suspected, radiography can easily identify this metallic foreign body.

Most ear canal foreign bodies can be removed by emergency physicians in the ED (1,2). The most commonly described techniques involve grasping the object with forceps, using a hook, loop, or curette to drag the object out of the ear canal and irrigation to wash the object out (1,5). A loop may be fashioned from a paperclip when more specialized tools are not available (6). Irrigation should only be undertaken if the tympanic membrane is intact (7). Cyanoacrylate applied to the blunt end of a cotton swab may be useful to remove a round smooth object such as a bead in a child who is cooperative or sedated (8). It is critical that the child be still and that the cyanoacrylate be used sparingly to avoid applying the adhesive to the ear canal. Procedural sedation improves the chances of successful removal in the ED (1).

Button batteries in the ear canal must be removed urgently to avoid continued tissue destruction (3), In the event that an ear canal foreign body other than a button battery cannot be removed in the ED, the patient may be referred to an ear, nose and throat (ENT) surgeon for removal using an otomicroscope in the clinic or operating room (9).

NASAL FOREIGN BODIES

CLINICAL PRESENTATION

Nasal foreign bodies tend to present in young children (median age of 2 to 3 years) (1,10). These children are asymptomatic about 50% of the time (1,10). Less common complaints include a foul odor, persistent nasal discharge, pain, discomfort, and bleeding. In about 10% of cases, unilateral nasal discharge is the sole presenting complaint (1,10). The most commonly encountered nasal foreign bodies include beads, plastic toy parts, corn kernels, and beans (10).

Children may also present to the ED with button batteries in their noses (4). Bilateral nasal magnets may adhere across the nasal septum causing pressure necrosis and perforation (11).

DIFFERENTIAL DIAGNOSIS

Young children with unilateral nasal discharge should be treated as if they have a nasal foreign body until proven otherwise (5). Nasal polyps may be mistaken for foreign bodies. Children who have a foul odor emanating from the mouth or nose may have halitosis, purulent pharyngitis, sinusitis, or a dental infection.

ED EVALUATION AND MANAGEMENT

A nasal foreign body can be identified by visually inspecting the nasal passages. Good lighting and a pediatric nasal speculum may be helpful.

The vast majority of nasal foreign bodies can be managed in the ED by emergency physicians (1,10). Sedation may be helpful in uncooperative children with large or adherent foreign bodies (1). The techniques for removal include grasping the object with forceps, using a hook, loop, or curette to drag the object forward, and suction applied directly to the foreign body (5). A positive pressure technique may be used whereby the parent applies pressure to the contralateral nostril and then blows into the mouth to expel the foreign body (12). Another technique is to insert a balloon catheter (such as a 6-French silicon Foley catheter or Fogarty vascular catheter) past the foreign body, inflate the balloon, and then withdraw the catheter with the balloon inflated. This is a good choice for large, round objects that are difficult to grasp and friable or fragmented materials such as clay or paper. Bilateral nasal magnets adherent across the nasal septum may be removed by placing the metal handle of a pair of forceps in each nostril to break the magnetic attraction and individually remove the magnets (13).

Essentially all children with nasal foreign bodies are discharged home (1). If a foreign body cannot be removed in the ED, outpatient referral to an ENT surgeon is appropriate in all cases except button

batteries and magnets adherent across the nasal septum, which require urgent removal to avoid tissue necrosis.

AIRWAY FOREIGN BODIES

CLINICAL PRESENTATION

Although aspirated foreign bodies are uncommon (5), they are most commonly seen in toddlers, and the most common symptoms include choking or coughing (5,14). Other signs and symptoms include dyspnea, fever, and wheezing. Stridor, hemoptysis, or completely asymptomatic presentations are uncommon. The most commonly reported aspirated objects are food-related, with peanuts accounting for about one-third of cases (5).

DIFFERENTIAL DIAGNOSIS

Symptoms associated with aspirated foreign bodies are nonspecific and may describe a wide variety of common pediatric ailments including viral upper respiratory tract infections, bronchiolitis, croup, asthma, pneumonia, and hydrocarbon aspirations.

ED EVALUATION AND MANAGEMENT

Definitively determining whether a child has aspirated a foreign body can be difficult because radiography and the physical examination are insensitive diagnostic tools (15). If the object is radiopaque, a two-view chest x-ray can clearly reveal the location of the foreign body in the trachea or bronchus. Unfortunately, about 85% of aspirated foreign bodies are radiolucent. If the radiology technologist can time it properly, inspiratory and expiratory chest x-rays may be helpful, revealing a normal symmetric inspiratory study but hyperinflation on the expiratory film on the side of the foreign body. Bilateral lateral decubitus films may reveal a failure of the mediastinum to shift downward toward the affected side. However, these techniques are insensitive and have high false positive rate (15). A careful history and physical examination and re-assessments

can help determine disposition in uncertain cases. Bronchoscopy is often both diagnostic and therapeutic (14).

Once an aspirated foreign body has been identified or is strongly suspected, consultation for bronchoscopy is indicated. A variety of pediatric specialists perform this procedure, including pulmonologists, intensivists, otolaryngologists, and surgeons. Aspirated foreign bodies and children with a clinical picture suspicious for aspirated foreign bodies should undergo urgent bronchoscopy.

GASTROINTESTINAL FOREIGN BODIES

CLINICAL PRESENTATION

Swallowed foreign bodies are common (16). Most children with subdiaphragmatic foreign bodies are asymptomatic, including those who ingest batteries (5,17). Developmentally delayed children may ingest large or sharp foreign bodies, present in an atypical fashion, or provide a limited history as a result of communication difficulties (18). The most widely studied esophageal foreign bodies are coins (5). More than 90% of children with esophageal coins are symptomatic before or at the time of presentation to the ED (5). Symptoms of esophageal foreign bodies include drooling, substernal pain, and a foreign body sensation. Recent years have seen an increase in magnet ingestion presentations to the ED commensurate with the increasing availability of small, high-powered rare earth magnets in the form of toys and accessories for both children and adults (19). Multiple ingested magnets can trap adjacent bowel loops and cause intestinal wall necrosis. The child may present with abdominal pain without fever, or symptoms of obstruction, volvulus, or perforation (19).

DIFFERENTIAL DIAGNOSIS

Although usually asymptomatic, subdiaphragmatic foreign bodies may present with abdominal pain or rectal bleeding (20). Conditions such as appendicitis, intussusception, Meckel diverticulum,

intestinal polyps, or other rare causes of abdominal pain must be included in the differential diagnosis.

ED EVALUATION AND MANAGEMENT

A traditional approach for evaluating a child with an ingested foreign body is to obtain x-rays from the nasopharynx to the bottom of the pelvis, looking for radiopaque foreign bodies. If a foreign body is identified, the critical question is whether the foreign body is esophageal, since these typically require treatment. If a child is asymptomatic, can eat and drink without apparent pain or difficulty, and has a negative set of x-rays, a subdiaphragmatic radiolucent foreign body is assumed. If the child has persistent foreign body sensation or pain in the substernal area or neck and the x-rays are unrevealing, the child may need to undergo esophagoscopy to evaluate for esophageal abrasions or a radiolucent esophageal foreign body. The use of handheld metal detectors has also been described in the evaluation of ingested coins. When used by emergency physicians, they are highly sensitive and specific for coin presence and highly accurate for coin localization (21). When the coin is localized to the stomach or beyond, children have been discharged without adverse events (22). This approach may save time and radiation exposure.

Subdiaphragmatic foreign bodies, including sharp objects and intact batteries, pass spontaneously the vast majority of the time in children with normal anatomies (18,23). Exceptions include very large or very long and pointed objects (typically ingested by developmentally delayed older school-aged children), children with abnormal gastrointestinal anatomy (e.g., an ileostomy), with multiple magnets in the intestines (19), with intestinal batteries that could be damaged or appear to be fragmenting on x-ray (17), and symptomatic children with evidence of peritonitis.

The vast majority of ingested foreign bodies, especially those that have been confirmed to be subdiaphragmatic, can be managed expectantly without further intervention unless symptoms such as vomiting, bloody stools, or abdominal pain develop. Although it has

been historically recommended that parents sift through stools until the foreign body is identified as having been passed, this process does little more than punish the parents. Children who have ingested multiple magnets typically require a laparotomy for magnet removal (19). Esophageal foreign bodies, especially button batteries, tend to need removal to avoid esophageal erosion (Fig. 273.1) (5). Coins above the thoracic outlet generally have low rates of spontaneous passage and risk airway compromise and obstruction; therefore, they should be removed urgently by a qualified specialist (24). Children with acutely ingested esophageal coins below the thoracic inlet may be observed for up to 16 hours for spontaneous passage, which occurs in up to 40% of cases (25).

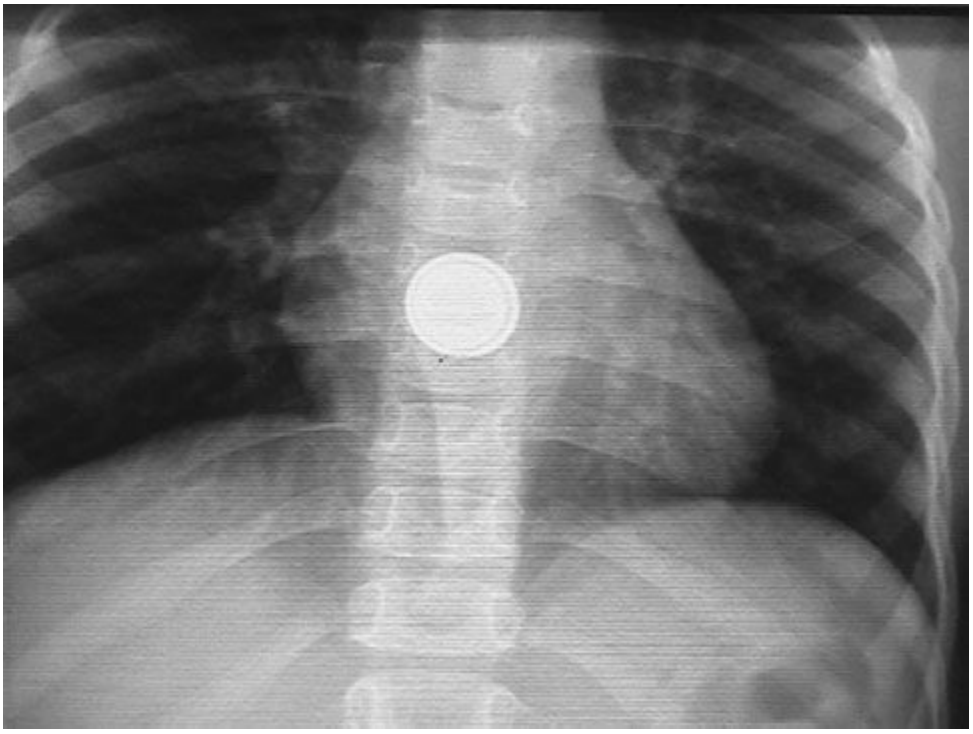

FIGURE 273.1 Radiograph of a large, flat disk battery in the distal esophagus of a young child. Note the faint circular area of relative radiolucency near the periphery of the object shadow. This characteristic target appearance distinguishes this object from the more homogeneous appearance of an ingested coin. (Photograph by Lance Brown, MD, MPH.)

CRITICAL INTERVENTIONS

- Arrange for urgent removal of button batteries in the ears, nose, or esophagus.
- Consider use of sedation to remove ear foreign bodies if not accomplished easily on first attempt.
- Arrange for urgent removal of multiple magnets that may adhere across tissue planes causing pressure necrosis. This may occur across the nasal septum or in the GI tract.

Common Pitfalls

- Delaying management of a disk battery or multiple magnet ingestion.
- Failure to use procedural sedation and appropriate equipment to manage ear foreign bodies.
- Failure to consider foreign body as the cause of unilateral nasal discharge.
- Relying on radiography to rule out an aspirated foreign body.

CHAPTER 274 Diabetic Ketoacidosis

Cristina M. Estrada and Timothy G. Givens

Diabetic ketoacidosis (DKA) is caused by either an absolute or a relative insulin deficiency accompanied by increased action of four counterregulatory hormones: glucagon, epinephrine, cortisol, and growth hormone (1,2). Counterregulatory hormone activity increases the patient's insulin resistance, thus compounding the effects of insulin deficiency. The results of this imbalance are hyperglycemia, dehydration, ketosis, and acidosis.

Precipitating events for this cascade include acute infection, inflammatory reactions, trauma, psychological stress, or medical noncompliance in patients known to have insulin-dependent diabetes mellitus (IDDM); recurrent DKA almost always occurs because of failure to take insulin as prescribed. Approximately 30% of cases of new-onset IDDM present as DKA (3); a high index of suspicion is required to make the initial diagnosis in infants and children. Mortality in DKA is most often associated with the development of cerebral edema, which occurs more frequently in children than adults (4–7).

CLINICAL PRESENTATION

Children with DKA may present variably making the diagnosis challenging in patients not previously known to be diabetic. Acutely, the child may appear moderately dehydrated and be misdiagnosed as having viral gastroenteritis or a urinary tract infection. Presenting symptoms include nausea, vomiting, abdominal pain, hyperpnea, fruity breath odor, dehydration,

lethargy, or coma. Polyuria, polydipsia, and polyphagia, three classic features of diabetes, coupled with weight loss should alert physician to consider DKA.

DIFFERENTIAL DIAGNOSIS

All patients presenting with vomiting should be queried for underlying histories of polyuria and polydipsia because new-onset diabetes with DKA may easily be mistaken for a routine case of gastroenteritis or a urinary tract infection. Occasionally, dehydrated children with gastroenteritis will have hyperglycemia and glucosuria caused by stress but do not have IDDM; since they are usually nonketotic (8).

The degree of hyperglycemia appears to be significantly associated with the severity of illness. However, the evidence is unclear as to whether patients with stress-induced hyperglycemia are at risk for future development of IDDM (8,9). If a history of diabetes is unclear or unavailable in a child with altered mental status, the differential diagnosis should widen to include intoxication, inborn errors of metabolism, Reye syndrome, sepsis, meningoencephalitis, nonketotic hyperglycemic coma, or hypoglycemic coma (10). In children with known IDDM, the differential diagnosis should focus on potential precipitants of DKA, such as bacterial infections, viral gastroenteritis, appendicitis, pancreatitis, or other acute intra-abdominal disorders.

ED EVALUATION

The evaluation of any child presenting with suspected DKA must address the following issues in a timely manner: (1) establishing the diagnosis, (2) assessing and correcting dehydration and electrolyte imbalance, (3) providing adequate insulin to restore normal metabolism, (4) searching for the precipitant cause of DKA, and (5) avoiding complications of therapy including cerebral edema, hypoglycemia, and hypokalemia.

DKA, as the name implies, has three components; hyperglycemia, ketosis, and acidosis. Patients may present with hyperglycemia

alone and with none of the other elements early in their course. Alternatively, they may present further along the continuum of illness and be hyperglycemic with ketonuria but have not yet become acidotic. It is therefore important to assess patients using clear criteria for hyperglycemia, ketonemia, and acidosis. Traditionally, patients have been deemed to be in DKA when the serum glucose level is greater than 300 mg/dL, ketonuria is detected by urine dipstick, and the pH measured via venous blood gas (VBG) is less than 7.30 or the serum bicarbonate is less than 15 mEq/dL. Patients who present earlier in their course of illness and are not in fulminant DKA may be candidates for less aggressive treatment. This may include additional doses of subcutaneous insulin on a sliding scale with close monitoring of glucose and urine ketones in consultation with an endocrinologist or primary care provider. It is important to appreciate the spectrum of presentations of DKA and how these may affect the ED evaluation and management.

Following a primary survey, the patient's degree of dehydration must be assessed. Estimates of dehydration are often underestimated, given the hyperosmolarity of the extracellular fluid in DKA patients. Relying solely on physical signs that correlate with extracellular volume loss (e.g., hydration of mucous membranes, skin turgor, and temperature) can be misleading and in general, one should assume at least 10%, or moderate, dehydration in all patients with DKA (1).

The interpretation of serum electrolyte levels must take into account the underlying physiologic derangements that accompany DKA. Measured serum sodium levels are often low secondary to the hyperosmolar state caused by hyperglycemia, which osmotically draws fluid into the intravascular space resulting in pseudohyponatremia. Correction of the serum sodium can be expected to occur without specific treatment as glucose levels fall during treatment for DKA. Serum potassium levels, on the other hand, may be elevated despite the patient's total body stores being depleted. In the presence of acidosis intracellular potassium ions are exchanged for extracellular hydrogen ions that may be lost via osmotic diuresis. Low-normal potassium levels in DKA may be

indicative of extreme total-body potassium depletion and continuous electrocardiographic monitoring for potassium-related cardiac dysrhythmias may be warranted.

KEY TESTING

- Initial serum testing including glucose, electrolytes, creatinine and urea nitrogen, blood gases, and hematocrit.
- A urinalysis should document the presence of ketones.
- The diagnosis of DKA is confirmed by the findings of hyperglycemia BG >300 mg/dL), a metabolic acidosis (pH <7.3 or HCO3 <15 mEq/L), ketosis.

ED MANAGEMENT

Treatment protocols for pediatric DKA vary considerably (10). Fluid replacement and correction of dehydration should begin as soon as possible. Formerly, volume expansion with a bolus of isotonic fluid such as normal saline, 20 mL/kg, was recommended during the first 1 to 2 hours of therapy. Because overly vigorous administration of fluids may precipitate a rapid fall in plasma osmolarity and is associated with the potential development of cerebral edema; pediatric treatment protocols now advise more conservative fluid replacement, on the order of 10 mL/kg during the first hour (11). Unless the patient is severely hemodynamically compromised, larger fluid boluses should be avoided (4).

Once the diagnosis of DKA has been confirmed, insulin administration should begin. Although insulin administration has been effective using intramuscular or subcutaneous routes, continuous low-dose intravenous infusion allows for slower, more even correction of hyperglycemia and is associated with fewer episodes of hypoglycemia than other routes of insulin administration (4). There is no evidence an initial bolus of intravenous insulin is helpful, and it may be harmful (1). Thus, a continuous intravenous infusion of insulin at a rate of 0.05 to 0.1 U/kg/hr is recommended. When mixing the insulin for infusion, the concentration of insulin should be at least 0.5 U/mL, and the

infusion line should be primed to overcome the effect of insulin binding to the intravenous infusion equipment. The addition of a single dose of the long-acting analogue insulin glargine to initial low-dose insulin infusion therapy may hasten resolution of acidosis and smooth the transition to subcutaneous insulin administration (12). Plasma glucose levels should be measured hourly and serum electrolyte concentrations and VBG every 2 to 4 hours. Calcium and phosphate concentrations should be checked every 8 hours. The rate of decrease in glucose should be no faster than 50 to 100 mg/dL/hr (1).

After the first hour, fluids should be adjusted to correct the free water deficit over the next 48 hours. This is accomplished with a solution of 0.45% sodium chloride (which closely approximates the fluid lost in DKA), with the addition of 40 mEq/L of potassium as either the chloride or phosphate salt. Some authors suggest that isotonic saline may be the most appropriate fluid for the first 24 hours of therapy (13). The overall guiding principle, independent of the particular choice of fluid, is the gradual correction of fluid and electrolyte deficits, with frequent monitoring of serum chemistries (1,14).

Dextrose is added to fluids when the plasma glucose levels approach 300 mg/dL; the desired goal is to maintain a glucose level between 200 and 300 mg/dL. At this point it is vital not to wean the insulin drip if the patient still has a clinically important anion gap. Glucose levels should be supported by the addition of dextrose-containing fluids and not by the tapering of insulin therapy. Some institutions use a “two-bag system” to easily titrate the dextrose concentration of intravenous fluids between 0% and 10% in response to the patient’s current serum glucose (15). In this technique, two bags of saline solution are prepared, one with 10% dextrose and the other 0% dextrose (simple normal saline solution). By regulating the rates of fluid administration from each bag, the amount of fluid can be maintained constant, whereas the glucose content of infusion can be adjusted to respond to changes in the patient’s serum glucose.

Hypophosphatemia and deficiency of 2,3-diphosphoglycerate are well-known features of DKA. They occur because of osmotic diuresis and phosphate competition with glucose for reabsorption at the renal tubules. Potassium phosphate has thus been proposed as an alternative to potassium replacement with the chloride salt. Correction of phosphate deficits has not been shown to clinically benefit children with DKA (2).

Both the benefits and the risks of the use of bicarbonate in the treatment of DKA remain unproven (16). The potential advantages of bicarbonate are improved myocardial function, reduction of potential for dysrhythmias, decreased insulin resistance, and a more rapid correction of acidosis. The major disadvantages of bicarbonate use are its potential for paradoxical central nervous system acidosis (caused by the increased diffusion of carbon dioxide across the blood–brain barrier), increased hemoglobin affinity for oxygen (which increases tissue hypoxia, because of reduced off-loading), and promotion of hypokalemia. Recent data show that bicarbonate therapy offers little benefit in terms of reducing the severity of acidosis, improving mental status, or correcting hyperglycemia (16). Rapid infusions of bicarbonate may produce hypokalemia and exacerbate the hyperosmolarity and have been associated with an increased incidence of cerebral edema in children (4). Therefore, bicarbonate, if is used at all, should be reserved only for severe and refractory acidosis or life-threatening hyperkalemia.

In spite of improvements in DKA management, mortality caused by cerebral edema has not changed (7). Data suggest a large percentage of patients in DKA have subclinical cerebral edema on computed tomography scans (3); however, clinically significant cerebral edema is reported in $<1\%$ of cases of DKA (5). Typically, signs of increased intracranial pressure present several hours into therapy, as the patient experiences a sudden decline in sensorium, headache, sluggish pupillary reflexes, or a change in vital signs despite improvement in metabolic and other clinical parameters.

Although cerebral edema has been thought to be related to aggressive fluid resuscitation in early DKA, there is no strong or consistent evidence implicating fluid administration as a primary

cause (17). What is known, however, in spite of a paucity of mechanistic evidence, is that children with new-onset IDDM and/or a prolonged period of untreated DKA are at increased risk for ultimately developing cerebral edema (3,17).

Once clinically apparent, cerebral edema is associated with a mortality rate of 60% to 80% and long-term neurologic morbidity in the majority of the rest. Hence, if cerebral edema becomes clinically evident, the patient should receive rapid aggressive intervention to reduce intra-cranial pressure—with intravenous mannitol (1 g/kg) or with 2 to 5 mL/kg of 3% saline (11). Intubation with mild hyperventilation should also be considered. Because of the devastating outcomes in patients who develop this complication, the need for frequent neurologic reassessments and early intervention cannot be over emphasized.

CRITICAL INTERVENTIONS

- A history of polyuria and polydipsia should be sought in every case of a child who is vomiting, particularly in very young children.
- Pediatric treatment protocols advise conservative fluid replacement, 10 mL/kg during the first hour.
- An initial bolus of intravenous insulin is not recommended because of concern about lowering the blood sugar too rapidly. A continuous infusion of intravenous insulin at a rate of 0.05 to 0.1 U/kg/hr is recommended.

DISPOSITION

Children in moderate-to-severe DKA should be admitted to a pediatric intensive or intermediate care unit because of the frequency and extent of monitoring required (1). Patients with new-onset IDDM should be admitted to a facility where age-appropriate diabetes education can be given.

Patients who can retain oral intake without vomiting and who are not significantly dehydrated or acidotic (pH >7.25) may be discharged home from the emergency department if appropriate

follow-up care can be arranged. Follow-up includes frequent telephone contact during the ensuing 24 hours with an individual knowledgeable in diabetes management.

Common Pitfalls

- Failure to administer adequate insulin, which may result from errors in insulin dilution or infusion. Concerns about therapy-related hypoglycemia are addressed by adding dextrose to the fluid replacement, not by slowing or stopping the insulin infusion.
- Failure to treat the precipitating process. Patients with refractory DKA should be thoroughly reexamined for a source of infection or intra-abdominal disorder, such as pancreatitis or appendicitis.
- Inadequate volume expansion from failure to monitor the patient's fluid input and output.
- Too-rapid correction of the hyperosmolarity may lead to cerebral edema and brainstem herniation.
- Inadequate potassium replacement during correction of acidosis, which leads to a shift of potassium into the cells and resultant hypokalemia.

CHAPTER 275

Metabolic and Endocrine Disorders

Jeffrey Hom

Metabolic disorders can be acquired or congenital, and early consideration is important in previously healthy neonates with apparent metabolic derangements that are not attributable to infectious, neurologic, toxicologic, or endocrinologic causes. This chapter focuses on the general approach to metabolic disorders and their diagnosis in the emergency department (ED).

CLINICAL PRESENTATION

Children with metabolic disorders frequently present with nonspecific symptoms. Differences in presentation can be subtle, especially in the neonatal period. Vomiting, alterations in neurologic status, and feeding difficulties are perhaps the most prominent features of metabolic diseases. Frequently, these patients are evaluated for common diagnoses, such as sepsis, that do not quite "fit." In neonates and young infants, although sepsis is always a consideration, metabolic disorders should also be considered, based on known historical and laboratory findings. Metabolic diseases often present with derangements that are discovered on a basic chemistry panel. These include abnormalities of glucose, sodium, potassium, and bicarbonate (the latter suggesting metabolic acidosis). Each of these abnormalities is linked to a disease or a constellation of symptoms that clinicians must recognize and address promptly.

DIFFERENTIAL DIAGNOSIS

Hypoglycemia

In children, infants, and term neonates older than 1 to 2 days of life, hypoglycemia is defined as a serum glucose concentration less than 40 to 45 mg/dL (1,2). The laboratory value should be interpreted in the context of the patients' clinical presentation and not as an isolated numerical value. Thus, symptomatic patients with a glucose level of 50 to 60 mg/dL warrant treatment. Glucose is the primary energy substrate for the brain. Its blood levels represent a balance between exogenous supply, endogenous gluconeogenesis, and glycogenolysis. Mobilization of glucose is mediated primarily by insulin, which stimulates glucose uptake in cells and glycogen synthesis; its actions are opposed by glucagon, cortisol, epinephrine, and growth hormone.

Symptoms of hypoglycemia generally fall into two categories: (1) those associated with activation of the autonomic nervous system (adrenergic) and (2) those associated with decreased cerebral glucose utilization (neuroglycopenic). Adrenergic symptoms are usually seen when there is a rapid decline in blood glucose and are accompanied by findings of tachycardia, tachypnea, vomiting, and diaphoresis. More familiar are neuroglycopenic symptoms, which are usually associated with slower or more prolonged hypoglycemia. These include poor feeding, altered mental status, lethargy, and seizures; they are usually evident in older children and adults, but in infants the presentation may be subtle and include only hypotonia, hypothermia, or poor feeding. Early detection hypoglycemia in newborns and infants lessens the risk of permanent brain damage. Hypoglycemia that requires acute resuscitation or intensive care unit management is associated with increased mortality in children (3,4). Persistent hyperinsulinemic hypoglycemia of infancy is a common cause of neonatal hypoglycemia and should be considered from the newborn period to 6 months of age (5). Causes of hypoglycemia are listed in Table 275.1.

TABLE 275.1
Causes of Hypoglycemia

Decreased Production/Availability of Glucose
Low glycogen stores
  Small for gestational age, prematurity
Malnutrition/fasting
  Malabsorption/diarrhea

Increased Utilization of Glucose
Hyperinsulinemic states
  Infant of diabetic mother
  Persistent hyperinsulinemic hypoglycemia of infancy
    Nesidioblastosis
    Islet cell adenoma/hyperplasia
  Beckwith–Wiedemann syndrome
Stress
  Infection/sepsis

Combined or Other Mechanism
Inborn errors of metabolism
Hormone deficiency
  Adrenal (glucocorticoid) insufficiency
  Growth hormone deficiency
  Glucagon deficiency
Iatrogenic
  Insulin/oral hypoglycemic therapy
  Poisoning (ethanol, propanolol, salicylates)
  Reye syndrome

Hyponatremia

Hyponatremia is one of the most common electrolyte abnormalities in hospitalized and critically ill children (1,6,7). It is defined as a serum sodium level less than 125 to 130 mEq/L, although clinical symptoms are not usually seen until the serum sodium falls below 120 mEq/L. Hyponatremia is caused by salt-losing states, including vomiting and diarrhea, diuretic excess, and adrenal insufficiency, or by excess total body water states, such as infection-induced syndrome of inappropriate secretion of antidiuretic hormone (SIADH), nephrotic syndrome, and cirrhosis. Factitious, or pseudohyponatremia, can occur in the context of hyperglycemia, hyperlipidemia, or hyperproteinemia. In children, hyponatremia is

commonly caused by excess gastrointestinal (GI) losses from prolonged vomiting or diarrhea or from inappropriately diluted formulas. Pyridoxine-dependent seizures are a rare cause of intractable seizures in neonates.

Symptoms of hyponatremia may include altered mental status, lethargy, vomiting, diarrhea, seizures, and circulatory collapse. Vomiting can be both a cause and a manifestation of hyponatremia. The presence of symptoms is dependent in part on the rate of change in serum sodium. Gradual or chronic progression of hyponatremia may not become clinically evident even at levels less than 110 mEq/L; conversely, less severe levels of hyponatremia may be symptomatic if the decline in serum sodium is rapid. Treatment should be geared toward the underlying disorder, and aggressive treatment with hypertonic saline should be initiated *if the patient is acutely symptomatic* (i.e., seizures or circulatory collapse). Central pontine myelinolysis is a potential complication of too rapid correction of hyponatremia, although it has been less frequently described in children than adults (2,6). Hyponatremia in the pediatric population tends to occur acutely rather than chronically, and most cases of central pontine myelinolysis occur after sodium is rapidly corrected in the context of chronic hyponatremia.

Metabolic Acidosis

Metabolic acidosis occurs via three major mechanisms: (1) loss of bicarbonate from the kidney or GI tract, (2) excess acid from endogenous production or an exogenous source, or (3) underexcretion of acid by the kidneys. Neonates and infants are more susceptible than older children and adults to acidosis due to a lower ability to reabsorb bicarbonate and limited maximum net acid excretion.

The significance of metabolic acidosis depends on whether it is a normal anion gap (AG) acidosis or an increased AG acidosis. The AG is the difference between serum sodium and the sum of serum chloride and bicarbonate $Na^+ - (Cl^- + HCO_3^-)$. The normal range of the AG is somewhat age dependent but in children is 12 ± 4. Causes of metabolic acidosis based on AG are listed in Table 275.2.

TABLE 275.2
Causes of Metabolic Acidosis

Normal ANION GAP
Gastroenteritis/diarrhea
Renal tubular acidosis
Adrenal (mineralocorticoid) insufficiency
Increased ANION GAP
Mudpiles
Methanol, uremia, DKA, paraldehyde, iron or INH, lactic acidosis, ethylene glycol, salicylates
Inborn errors
Carbohydrate, amino acid, or fatty acid metabolism
Starvation
Chronic renal insufficiency

Clinical manifestations of metabolic acidosis are nonspecific and include altered mental status, vomiting, and poor perfusion. Tachypnea as a compensatory mechanism can be an important sign alerting the ED physician of possible metabolic acidosis. Breathing quality and depth can range from mild and shallow to the deep Kussmaul respirations of the severely acidotic patient. Treatment consists of appropriate fluid resuscitation and specific therapy of the underlying cause of the acid–base disturbance.

Diagnostic Entities

Adrenal Insufficiency

Adrenal insufficiency is either acquired or inherited and caused by primary adrenal disease or secondary to pituitary suppression. Congenital adrenal hyperplasia (CAH) is one of the primary causes of newborn primary adrenal insufficiency, whereas Addison disease is a more common cause in children and adolescents. Secondary adrenal insufficiency is more common in older children and frequently is a sequel of exogenous steroid use. Acute adrenal insufficiency or crisis occurs when the adrenal glands, in response to stress, fail to produce adequate glucocorticoid and mineralocorticoid. The common ED presentation involves a patient treated for a chronic disease, such as

asthma, who has recently discontinued steroids and is exposed to a precipitating stressor (e.g., infection). In patients with unexplained electrolyte abnormalities or hypotension, a careful history eliciting previous steroid use is the key to diagnosis.

CAH refers to a group of inherited defects in adrenal biosynthesis of cortisol. Low cortisol production stimulates pituitary production of adrenocorticotropic hormone (ACTH), which causes the characteristic hyperplasia of the adrenal cortex. Depending on the affected enzyme in the biosynthetic pathway, the synthesis of other steroids such as mineralocorticoids (aldosterone) or androgens may also be affected, and clinical expression of disease varies correspondingly. Deficiency of 21-hydroxylase (21-OH) accounts for up to 95% of CAH cases, and discussion here is limited to this particular form of CAH which occurs in 1 in 10,000 to 20,000 live births worldwide (8). Up to 75% of affected newborns have the "classic" salt-losing virilizing variant, which is associated with aldosterone deficiency and androgen overproduction; up to 25% have the nonsalt-losing virilizing type. The degree of virilization and other clinical signs is usually greater in the salt-losing variant.

Many states now screen newborns for CAH; however, these results may not be available for several weeks, and an acute adrenal crisis may occur during this time. Males are particularly prone to a missed diagnosis since their genitalia may appear normal at birth, in contrast to females, who usually exhibit ambiguous genitalia. Another physical examination sign is hyperpigmentation, which is caused by the accumulation of a corticotropin precursor that stimulates melanocytes; hyperpigmentation may be present in the axilla and scrotal or labial areas. Symptoms of the classic salt-losing type may begin 1 to 2 weeks after birth and include weight loss, poor feeding, vomiting, polyuria, and dehydration.

Acute adrenal insufficiency, whether acquired or secondary to classic CAH, is associated with hyponatremia, hyperkalemia, and hypoglycemia. A normal anion gap metabolic acidosis is often seen due to aldosterone deficiency. Unexplained hypotension unresponsive to intravenous (IV) fluids is another sign of steroid deficiency. In cases involving infection or trauma, the clinical

progression can be rapid and fulminant, leading to altered mental status, hypotension, or death. Treatment should be geared toward aggressive fluid resuscitation and rapid initiation of stress doses of corticosteroids. Prior to treatment, blood should be collected, if possible, for nonemergent testing of specific endocrine hormones and metabolites.

Thyroid Disorders

Hyperthyroidism in children is almost always caused by Graves disease (diffuse toxic goiter), an autoimmune disorder that produces thyroid-stimulating hormone (TSH) receptor antibodies, causing increased thyroid hormone secretion (9). Nearly 5% of all patients with hyperthyroidism are adolescents younger than 15 years of age. Unlike adults, children with hyperthyroidism usually have months of indolent symptoms prior to diagnosis. Personality or emotional disturbances may be the earliest symptoms, followed by more classic symptoms of weight loss, heat intolerance, diaphoresis, palpitations, diarrhea, and amenorrhea. A goiter is present in nearly all cases, and exophthalmos, tachycardia, and hypertension are common. Thyroid storm can occur in the pediatric population; it consists of extreme signs and symptoms of hyperthyroidism combined with fever and altered mental status. A stressor such as infection, trauma, or dehydration usually precipitates thyroid storm. Thyroid storm is life-threatening, and management, as in adults, should be early and aggressive.

Neonatal thyrotoxicosis (also known as congenital hyperthyroidism) is caused by in utero passage of thyroid-stimulating immunoglobulins from mother to fetus. In most cases, it is caused by maternal Graves disease and occurs in up to 10% of infants born to these mothers (10). Euthyroid mothers treated for hyperthyroidism remain at risk for having a newborn with thyrotoxicosis. These infants are commonly born preterm with low birthweight, microcephaly, and craniosynostosis. The infants usually present within a few days of life, but sometimes 10 days or more after birth. Symptoms are transient and last less than 6 to 12 weeks; the duration depends on the persistence of maternally transmitted

immunoglobulins. Symptoms include vomiting, diarrhea, poor feeding, weight loss, sweating, and irritability. Most have a goiter, and many also have exophthalmos, hyperthermia, tachycardia, hepatomegaly, and jaundice. Although transient, neonatal thyrotoxicosis can be life-threatening, usually from heart failure, with a reported mortality of up to 20% (11).

Hypothyroidism does not occur with acute signs or symptoms and is rarely classified as an emergent condition. Because of laboratory errors in newborn screening, congenital hypothyroidism may occasionally be missed, making early ED detection and treatment (within the first few weeks of life) important to prevent irreversible brain damage. Classic symptoms include prolonged jaundice, poor feeding, constipation, somnolence, and hypothermia. Classic signs include coarse puffy facies, large fontanelles, macroglossia, hypotonia, jaundice, and a distended abdomen with umbilical hernia.

Inborn Errors of Metabolism

These diverse hereditary disorders all involve gene mutations, of an enzyme or transport system, causing clinically significant blocks in metabolic pathways that result in accumulations of toxic metabolites. Because of the large number of inborn errors of metabolism (IEMs), the reported incidence of these disorders varies greatly, ranging from 1 in 15,000 for PKU to 1 in 100,000 for organic acidemias (12,13). It is now possible to screen for many of these defects prior to birth. Many IEMs manifest clinically in the newborn period or shortly thereafter, and failure to make an early diagnosis may lead to permanent brain damage and death if specific treatment is not initiated. There are only a few IEMs that are amenable to specific emergency treatment. The most common clinical manifestations in the neonatal period include vomiting, neurologic abnormalities, metabolic acidosis, and hypoglycemia (1). These nonspecific findings can mimic many other disorders, including sepsis or adrenal crisis. An IEM should be considered, however, in a previously normal neonate who presents with an acute clinical deterioration. The presence of infection does not exclude the possibility of an IEM, as

patients with IEM may deteriorate and become septic quickly. Standard laboratory values, particularly blood ammonia, electrolytes, and urinalysis, can be helpful in further classifying the IEM and tailoring treatment in the ED (see Fig. 275.1).

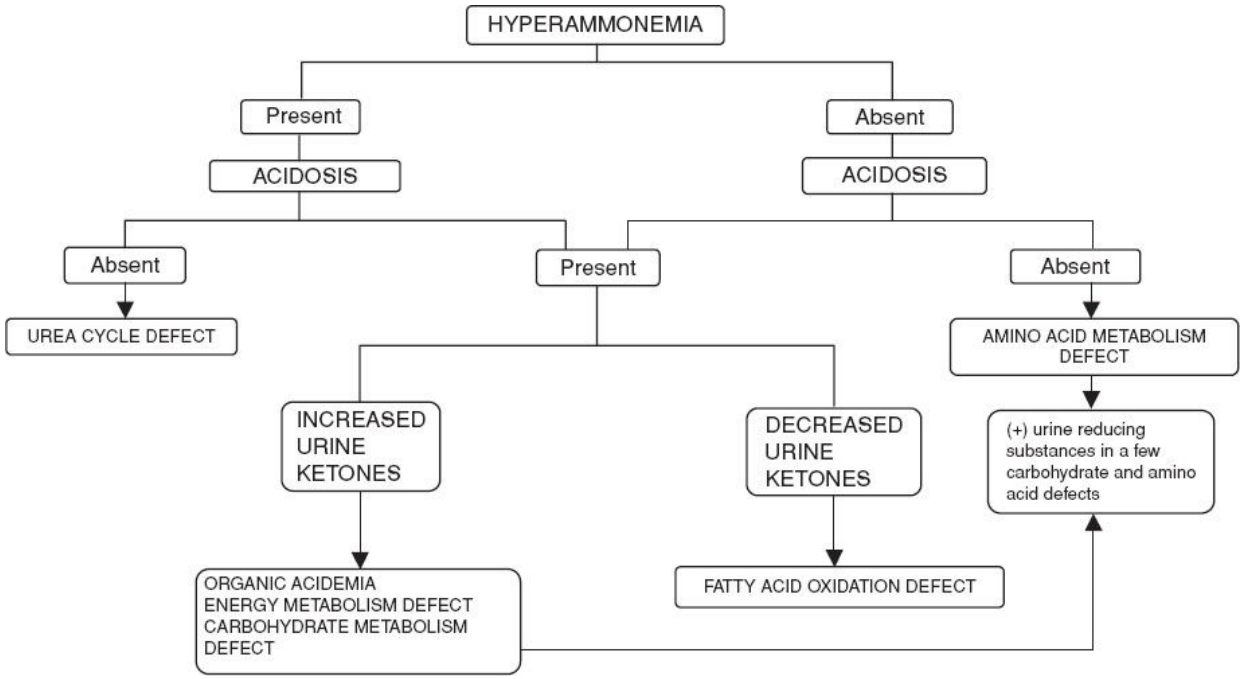

FIGURE 275.1 Diagnostic pathway for inborn errors. Note: Exceptions to above pathway exist. (Modified from Brousseau T, Sharieff G. The critically ill newborn. *Crit Dec Emerg Med.* 2003;18:1–7.)

IEMs can be divided into disorders of amino acid metabolism (phenylketonuria, nonketotic hyperglycinemia); fatty acid oxidation or metabolism (acyl-coenzyme A dehydrogenase deficiency, primary carnitine deficiency), energy metabolism (primary lactic acidemias); and carbohydrate metabolism (glycogen storage diseases, galactosemia). The organic acidemias (methylmalonic, propionic, and isovaleric acidemias, maple syrup urine disease) are a specific group of disorders of amino and fatty acid metabolism in which high levels of nonamino organic acids accumulate in the serum and urine.

Most patients with IEMs exhibit symptoms as newborns after feedings have been initiated, but a minority may go undetected into

childhood demonstrating only psychomotor delay until a stressor causes their condition to deteriorate. Recurrent vomiting, dehydration, and acute metabolic encephalopathy are common clinical manifestations. Neurologic symptoms can range from hypotonia to seizures to frank coma. Intractable seizures are characteristic of nonketotic hyperglycinemia and pyridoxine-dependent seizures. Hepatomegaly is a common physical examination finding and can be pronounced in glycogen storage diseases and galactosemia. The risk of *Escherichia coli* sepsis and liver failure is also increased in patients with galactosemia. A particular odor in body fluids is associated with certain specific disorders. Maple syrup urine disease is named for its characteristic sweet sugar odor; isovaleric acidemia is associated with a "sweaty feet" scent; and methylmalonic and propionic acidemias can result in a fruity ketotic odor similar to that of diabetic ketoacidosis. Metabolic acidosis with an increased AG is common in many IEMs. Hypoglycemia is also common and can be pronounced, particularly in glycogen storage diseases and defects of fatty acid oxidation (14).

Hyperammonemia is most commonly seen in organic acidemias and urea cycle defects. Urea cycle defects are a specific class of IEMs that are associated with hyperammonemia caused by the inability to detoxify ammonia and convert it to urea. These include ornithine transcarbamylase (OTC) deficiency, arginase deficiency (argininemia), and argininosuccinic acid synthetase deficiency (citrullinemia). The clinical manifestations parallel those seen in other IEMs. Neonates frequently present after a few days of protein feeding (of either breast milk or formula); older infants and children may present with recurrent vomiting, ataxia, or developmental delay. Tachypnea is common because ammonia may stimulate the respiratory center. The degree of hyperammonemia tends to be greater than that seen in organic acidemias. Blood ammonia is usually more than 200 μmol/L (generally greater than three to five times the upper range of normal) (1,2). Although sicker infants tend to have higher ammonia levels, there is no strict correlation between the ammonia level and clinical severity of disease. The degree of neurologic impairment is thought to be related to the rate of increase

and duration of hyperammonemia. Blood urea nitrogen (BUN) is usually low, but a normal BUN does not exclude a urea cycle defect. Metabolic acidosis does not occur with these disorders unless there is concurrent dehydration from another illness. The lack of acidosis is helpful in differentiating urea cycle defects from many of the other IEMs.

ED EVALUATION

Questions about prenatal care and maternal medications may yield clues to the diagnosis of an endocrine disorder. Newborn screening test results, as well as a history of consanguinity or sudden infant death in the immediate family, are important to know when considering a potential IEM. Feeding difficulties, weight loss, or association of symptoms with dietary intake or particular types of food are always important historical elements in newborns. Vomiting is a prominent feature in most metabolic disorders.

The physical examination should focus on the neurologic and circulatory status. Alterations in consciousness can range from mild lethargy to seizures and coma. Hypotonia with poor suck and Moro reflexes are frequently seen. Dehydration with tachycardia, poor perfusion, or hypotension should be recognized early and treated aggressively. Tachypnea is a characteristic sign in acidotic patients, and the degree of tachypnea frequently correlates with the severity of acidosis. Unusual or peculiar body fluid odors suggest IEMs. Hepatomegaly and jaundice may be prominent in glycogen storage diseases and galactosemia.

Emergent diagnostic testing should begin with bedside glucose testing, which should be verified by standard laboratory testing. Electrolytes, and calculation of the AG, help with diagnostic classification (see Table 275.2). Acid–base status can be more precisely measured with an arterial blood gas, although in the absence of hypoxia or poor perfusion, a venous or capillary measurement may be adequate in infants (15,16). An increased AG is the most sensitive and specific sign for organic academia, especially when the AG is greater than 20 (1). Serum calcium, magnesium, and liver function tests should also be obtained. Urinalysis will reveal the

presence or absence of ketones, which can help to differentiate particular metabolic disorders; the lack of an appropriate ketonuric response to metabolic acidosis is indicative of a fatty acid oxidation defect. The pH of urine is normally less than 5 in organic acidemias, while the most common urea cycle defect, ornithine transcarbamylase deficiency, may contain urinary orotic acid crystals. The finding of urine reducing substances in the absence of glycosuria is indicative of galactosuria and presumptive galactosemia. Urine reducing substances can also be seen in a few disorders of amino acid metabolism, such as tyrosinemia. Urine electrolytes and osmolality can better classify a hyponatremic disorder. Serum osmolality, both measured and calculated along with drug screens and levels, can help to exclude a toxicologic cause. Concurrent with these studies should be standard investigations for infection, including a complete blood count (CBC), cerebrospinal fluid studies, and body fluid cultures.

Blood ammonia level should be obtained in any altered patient in whom metabolic disease is suspected. Ammonia is significantly elevated in urea cycle defects and many of the organic acidemias. Mild transient elevation of ammonia is common in asymptomatic neonates, especially premature infants. To avoid falsely elevated levels, ammonia testing must be completed within 30 minutes of the blood draw. Lactate and pyruvate levels can be of use, although both acids can be elevated in sepsis and IEMs. The lactate-to-pyruvate ratio tends to be increased in sepsis ($>$10:1), whereas in many IEMs, such as primary lactic acidosis, the ratio is usually normal. Because stat thyroid function testing is now available in many laboratories, these tests should be initiated in the ED when indicated. Testing should include levels for TSH and free thyroxine (T_4).

Additional archival body fluid samples should be appropriately collected and stored if an undiagnosed metabolic disease is considered in the ED, preferably prior to initiation of treatment. For adrenal insufficiency and CAH, additional blood studies to consider include cortisol, ACTH, 17-hydroxyprogesterone, aldosterone, renin, insulin, and growth hormone. For organic acidemias and other defects in amino acid and fatty acid metabolism, quantitative levels

of blood amino acids and urinary amino and organic acids will aid in definitive diagnosis. Although these tests are not emergent, the emergency physician may on occasion be requested to order these studies by a consultant.

KEY TESTING

- Initial bedside fingerstick
- Basic metabolic panel
- Arterial blood gas (if not available, obtain venous blood gas)
- Ammonia level

ED MANAGEMENT

ED management begins with the standard ABCs (airway, breathing, and circulation). Poorly perfusing or hypotensive patients require IV fluid resuscitation, and antibiotics should be administered empirically for suspected sepsis. Overaggressive fluid resuscitation should be avoided in normotensive infants, as well as in patients with diabetic ketoacidosis because of the suspected risk of cerebral edema.

Acute treatment for hypoglycemia begins with IV glucose. The recommended bolus dose ranges from 0.25 to 1 g/kg. A midlevel dosing range of 0.4 to 0.5 g/kg glucose translates to approximately 4 mL/kg of 10% dextrose-containing solution, 2 mL/kg of 25% dextrose-containing solution, or 1 mL/kg of 50% dextrose-containing solution. Generally, a 10% solution is used in neonates and infants to minimize the risk of causing vascular injury with more concentrated fluids. In toddlers and children a 25% solution may be used and in adolescents a 50% solution. Continuous glucose infusion should follow bolus administration, especially in neonates, to maintain normal glucose levels. The normal glucose requirement in a neonate is 6 to 10 mg/kg/min, which is roughly equivalent to an infusion of 10% dextrose-containing solution at 1.5 times maintenance rate. Glucose levels should be rechecked frequently (every 1 to 2 hours) and the infusion rate adjusted accordingly. If hypoglycemia persists despite boluses and infusions in an infant, a hyperinsulinemic state

should be considered; this may be treated with glucagon 0.1 to 0.2 mg/kg (up to 1 mg) parenterally. Because it can be given intramuscularly, glucagon can be particularly helpful when IV access is difficult or delayed. Glucagon is not effective in patients lacking adequate glycogen stores (e.g., those with inherited storage diseases) (17). Hydrocortisone 2 to 3 mg/kg or 25 to 50 mg/m^2 can also be considered for refractory hypoglycemia (2).

Hyponatremia should be treated with 3% hypertonic saline (514 mEq/L) only if there are seizures or coma. A dose of 5 mL/kg over 10 to 15 minutes should raise the sodium level by approximately 5 mEq/L; smaller additional doses of 2 to 3 mL/kg can be considered if no clinical improvement is seen. Acute correction to 125 mEq/L should alleviate symptoms in most cases. Following the acute correction, sodium levels should be slowly corrected to normal at a rate of 0.5 mEq/L/hr (maximum 12 mEq/L/d) using a 0.9% normal saline infusion. If SIADH is suspected, consider fluid restriction to two-thirds maintenance and administration of furosemide 1 to 2 mg/kg. Pyridoxine 100 mg IV should be considered for neonates with intractable seizures where isoniazid overdose is a possibility (2,18).

Acute adrenal insufficiency is treated with stress doses of corticosteroids; Table 275.3 lists various options. Hydrocortisone is the steroid of choice, having equal glucocorticoid and mineralocorticoid effects; cortisone is an alternative but cannot be given IV. The stress dose of hydrocortisone, three to four times the physiologic dose, is 25 to 50 mg/m^2 (approximately 2 to 3 mg/kg). Dexamethasone has no mineralocorticoid effect and thus does not interfere with diagnostic ACTH-stimulation testing; it is therefore preferred over hydrocortisone in normotensive patients with an unconfirmed diagnosis. An oral mineralocorticoid such as fludrocortisone can be started after initial stabilization with IV fluids and glucocorticoids. Hyperkalemia should self-correct with fluids and steroid therapy and rarely requires specific treatment.

TABLE 275.3
Corticosteroids for Adrenal Insufficiency

Drug	Dose	Potency Effect (per mg)	
		Glucocorticoid	Mineralocorticoid
Glucocorticoid			
Hydrocortisone	25–50 mg/m^2 IV/IM Or Infant: 25 mg Child: 50 mg Teen: 75 mg	1	1
Cortisone	1 mg/kg IM	0.8	1
Dexamethasone	0.1–0.2 mg/kg IV/IM	40	none
Mineralocorticoid			
Fludrocortisone	0.1 mg PO daily	15	400

IV, intravenous; IM, intramuscular; PO, by mouth.

There are many available therapeutic interventions for neonatal hyperthyroidism and thyroid storm. β-Adrenergic blockade can be achieved with propanolol 0.01 mg/kg/dose IV titrated to clinical effect; alternative oral dosing is 2 mg/kg/d in three to four divided doses. Thyroid hormone synthesis can be blocked using propylthiouracil 5 to 10 mg/kg/d or methimazole 0.5 to 1 mg/kg/d, both in three divided oral doses. Iodine can be given in the form of Lugol solution (8 mg iodine/drop) 1 to 3 drops daily. Iodine should be started at least 1 hour after administering an antithyroid drug such as propylthiouracil to avoid increasing thyroid gland stores before the antithyroid effect occurs. Glucocorticoid treatment with hydrocortisone or prednisone may also be helpful in severe cases.

Treatment for IEMs consists of general measures as well as specific medications if a probable type of IEM is suspected. Unless the infant has a known IEM and is already on a special formula, all dietary intakes should be withheld and feedings reintroduced only after consultation with a specialist. IV fluid that contains dextrose may be indicated, particularly if a urea cycle defect is suspected, because stimulating endogenous insulin will minimize protein catabolism and ammonia production. After appropriate fluid boluses of normal saline

to correct shock, most IEMs can be managed with a standard IV fluid consisting of 10% dextrose in normal saline at 1.5 times maintenance. Metabolic acidosis unresponsive to IV fluids should be treated with sodium bicarbonate boluses of 1 to 2 mEq/kg. The rapid removal of toxins may be life saving in some cases, particularly with severe hyperammonemia. Hemodialysis to remove excessive ammonia is more effective than peritoneal or other extracorporeal routes (1,2). Temporizing empiric therapy with arginine, with or without sodium benzoate/phenylacetate, can reduce ammonia levels acutely in most urea cycle defects. Table 275.4 lists specific therapies to consider when suspecting particular IEMs.

TABLE 275.4
Specific Therapies for Inborn Errors of Metabolism

Drug	Dose	Indication
Arginine HCL 10%[a]	210–600 mg/kg IV	Urea cycle defects
Biotin	10 mg IV or PO	Organic acidemias
Carnitine	50–100 mg/kg IV or PO	Fatty acid defects, organic acidemias
Pyridoxine	100 mg IV	Pyridoxine-dependent seizures
Sodium benzoate[a] and/or phenylacetate[a]	250 mg/kg IV	Urea cycle defects
Thiamine	25–100 mg IV	MSUD, primary lactic acidosis

[a]Can infuse over 1 to 2 hours in dextrose-containing solution.
IV, intravenous; PO, by mouth.
Data from Kwon (2) Ozand (14), and Weiner (13).

CRITICAL INTERVENTIONS

- Bedside glucose testing and frequent glucose monitoring (every 1 to 2 hours based on diagnosis).
- Dextrose solution greater than 12.5% will require central access.
- Recognition of the signs and symptoms of thyrotoxicosis or thyroid storm in an infant.
- Correction of hyponatremia in cases of dehydration and GI losses with normal saline over 24 hours

- Sodium bicarbonate for severe refractory metabolic acidosis if an IEM is suspected.
- Rapid treatment of severe hyperammonemia with arginine and emergent hemodialysis.

DISPOSITION

Most symptomatic patients with a known or suspected metabolic disorder require hospitalization, typically in an intensive care setting for frequent monitoring of metabolic parameters and neurologic status. Prompt consultation should be initiated with a pediatric endocrinologist or metabolic specialist. If appropriate resources are unavailable, transfer should be arranged with a pediatric center skilled in managing metabolic disorders. This should be done expeditiously after resuscitation and empiric treatment for suspected disorders have been started. In the event of a failed resuscitation or imminent death in a patient with suspected IEM, permission for autopsy and specimen testing should be discussed with parents. Perimortem samples to consider include frozen blood and urine specimens, skin biopsy, and needle liver biopsy (1). These studies may allow for appropriate genetic counseling for family members and future siblings.

Common Pitfalls

- Failure to consider a metabolic disorder in a previously healthy infant with acute clinical deterioration.
- Delayed recognition and treatment of hypoglycemia and hyperammonemia.
- Failure to recognize acute adrenal insufficiency in a patient with refractory hypotension.

CHAPTER 276 Kawasaki Disease

James A. Wilde

Kawasaki disease (KD), also known as *mucocutaneous lymph node syndrome,* was first described in Japan in 1967 (1) and reported in the United States literature in 1974 (2). Although initially thought to be a new disease, KD was soon recognized to be clinically indistinguishable from infantile periarteritis nodosa (3). The disease is primarily a vasculitis that affects the coronary arteries most significantly, but it can also produce pathology in the central nervous system, liver, gallbladder, lungs, and digits.

Three to five thousand cases of KD are estimated to occur in the United States annually (4). Children younger than 5 years of age account for 80% of cases, but the disease has also been reported in young adults (5,6). The peak incidence is in the second year of life. Intensive efforts to identify the causative agent have failed to yield an etiology, although certain clinical and epidemiologic features favor an infectious cause.

No specific diagnostic assay can definitively identify a case of KD, so the diagnosis must be made presumptively based on clinical features and laboratory findings. Some children have been described with an incomplete form of KD that does not fit the classic case definition, making identification still more challenging (7–9). About 25–30% of untreated patients with KD develop coronary artery ansurysms, compared to 5% to 8% of those treated with the currently recommended regimen of intravenous immune globulin (IVIG) and aspirin (10). The overall mortality rate is 1% to 3% in untreated KD, (11) but as low as 0.08% with treatment.

CLINICAL PRESENTATION

Classic KD is diagnosed by clinical criteria originally described by Kawasaki, with only slight modifications. These criteria include fever of at least 5 days duration, at least four of five physical findings, and no other explanation for the illness (Table 276.1). The fever is generally >39°C, spiking, remittent, and prolonged in untreated patients, with some children remaining febrile for 2 to 4 weeks. Another commonly reported finding is extreme irritability beyond that seen in more common febrile illnesses (12).

TABLE 276.1
Diagnostic Criteria for Kawasaki Disease

Fever of at least 5 days duration
PLUS
Presence of four of five physical findings:
Bilateral, nonpurulent conjunctival injection
Inflammatory changes of the lips and oral mucosa
Erythema or swelling of the hands or feet
Nonvesicular rash, primarily truncal
Cervical lymphadenopathy, usually unilateral
AND
Illness not explained by other known disease

The conjunctivitis is primarily bulbar, spares the area around the limbus, and is not associated with an exudate. Changes in the lips may include erythema, bleeding, dryness, and fissuring. The oral mucosa may show erythema with a strawberry tongue, but exudates and oral ulcerations are not found. Hands and feet may show edema, erythema, or both, primarily on the palms and soles, with characteristic desquamation 1 to 2 weeks after the onset of the illness. The rash can be quite variable, but it is most commonly diffuse, maculopapular, and erythematous.

Cervical lymphadenopathy is usually unilateral, is nonfluctuant, and is defined by a node diameter of at least 1.5 cm. Each of the clinical criteria described above is found in approximately 90% of

cases, with the exception of cervical lymphadenopathy, which is noted in only 50% to 75% of cases.

Multiple organ system involvement has been reported, including pericarditis, myocarditis, arthritis, cerebrospinal fluid pleocytosis (13), peripheral extremity gangrene (14), pulmonary infiltrates, and hydrops of the gallbladder (12). A desquamated, erythematous, perineal rash in the first 3 to 4 days of illness is an early finding that can potentially be helpful in making the diagnosis, although it is not specific for KD (15).

Approximately 1 to 2 weeks after the onset of the acute symptoms, resolution of the fever, rash, and lymphadenopathy can be expected, although the conjunctival injection often persists. It is during this subacute stage that desquamation of the digits occurs. This is also the stage at which coronary artery aneurysms develop and the risk of sudden death is highest.

Incomplete KD, formerly known as atypical Kawasaki disease, was first described in a number of case reports and case series in the early 1980s (7). Most of these patients were younger than 6 months of age, but cases in older children have also been reported (9). Incomplete KD is a febrile illness that does not meet the case definition for KD but can result in cardiac sequelae at least as severe as those of typical KD (16). In most cases reported to date, one to three of the physical findings typical of KD have been present, but several cases of incomplete KD have been manifested solely by fever.

DIFFERENTIAL DIAGNOSIS

There are several diseases that can mimic KD, but careful attention to the clinical criteria, as outlined above, can help to avoid misdiagnosis. Among these diseases are scarlet fever, measles, toxic shock syndrome, Stevens–Johnson syndrome, leptospirosis, and Rocky Mountain spotted fever. Tonsillar exudates suggest an illness caused by group A streptococci, such as scarlet fever, as does the characteristic scarlet fever rash. Prominent respiratory symptoms, particularly cough, should suggest measles. Many of the symptoms

of toxic shock are similar to those of KD, but hypotension is an uncommon finding in KD unless heart failure secondary to severe carditis has developed.

Recent exposure to inciting drugs, the presence of oral lesions, an exudative conjunctivitis, and the typical “target lesion” rash can serve as clues to the diagnosis of Stevens–Johnson syndrome. The centripetal spread of a petechial rash that begins on the hands or feet, severe myalgias, and seasonal and epidemiologic clues may point to Rocky Mountain spotted fever. Chills, myalgia, and abdominal pain may lead to the diagnosis of leptospirosis. Serologic tests are of limited value in the acute stage of any of these illnesses, but they can be helpful during the recovery phase for retrospective diagnoses.

In the emergency department (ED), the diagnosis of KD is usually one of exclusion and is often not considered until the patient has presented to a clinic or emergency setting multiple times. In one recent study, there was a mean of 7.9 days between onset of illness and diagnosis. Independent predictors of delay in diagnosis included age younger than 6 months and a presentation of incomplete KD (17).

ED EVALUATION

Immediate workup of a suspected case of KD should include a complete blood count and differential, platelet count, blood cultures, erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP), and a chemistry panel including serum transaminases, total protein, and albumin. Elevation of acute phase reactants such as ESR or CRP is virtually always present during the acute stage (12) and strongly supports the diagnosis of KD or incomplete KD when seen in combination with a consistent set of clinical signs and symptoms. White blood cell counts are usually elevated, with polymorphonuclear cell predominance, and leukopenia is uncommon. Platelet counts are usually normal in the acute stage but after a week may be markedly increased, occasionally to more than 1 million per microliter.

Laboratory values may yield mixed results, but a few findings are worthy of note. A GGT level may be elevated in up to 70% of children at risk for KD. In addition, serum transaminases are often two to three times normal in patients with KD. Marked rises in serum immunoglobulin levels in the acute stage may result in an elevation in the total serum protein level; serum albumin is often decreased. Urinalysis may reveal sterile pyuria, with ≤10 white blood cells per high-power field. Urine should be collected without a catheter because the pyuria is a reflection of urethral inflammation. Last, a lumbar puncture may reveal aseptic meningitis (13).

Further workup in patients with likely KD should include a baseline electrocardiogram to identify evidence of myocarditis or pericarditis. A baseline echocardiogram should also be obtained but should not delay therapeutic interventions.

Young children and infants with unexplained prolonged fever should be evaluated for incomplete KD. The American Academy of Pediatrics and the American Heart Association have suggested a laboratory-based algorithm to aid clinicians in making this diagnosis (Table 276.2) (12).

TABLE 276.2
Algorithm for the Diagnosis of Incomplete Kawasaki Disease

Fever ≥5 days *and* two to three clinical criteria consistent with KD *and* no symptoms inconsistent with KD *and* CRP ≥3.0 mg/dL and/or ESR ≥40 mm/h *and*

≥3 supplemental laboratory criteria*:

- Albumin ≤3.0 g/dL
- Elevation of alanine aminotransferase
- Platelets after 7 days illness ≥450,000/mm^3
- White blood cell count ≥15,000/mm^3
- Urine ≥10 white blood cells per high-power field

*Infants ≤6 months old and fever ≥ 7 days without explanation can be diagnosed with IKD without additional clinical criteria or supplemental laboratory criteria if they have a positive echocardiogram.

Source: From Newburger JW, et al. (18)

ED MANAGEMENT

Children who meet the clinical case definition of KD and who have evidence for inflammation as demonstrated by an elevated ESR or CRP should be admitted to the hospital and treated for KD. High-dose IVIG when administered early in the course of disease at a dose of 2 g/kg over a 10-hour period has been shown to substantially reduce the incidence of coronary artery aneurysms (11). High-dose aspirin at 100 mg/kg/day in four doses is also started on admission and is continued until the acute phase has resolved. Corticosteroids are not currently recommended for initial therapy but may play a role in refractory cases (19).

In the ED, uncomplicated KD requires no more than supportive management such as an antipyretic for fever and intravenous fluids for rehydration and maintenance, although more serious manifestations such as cardiovascular decompensation may require more aggressive supportive treatment.

Infants and children who present with prolonged fever and fewer than four of the classic clinical findings of KD may have incomplete KD. Those meeting the criteria for incomplete KD should be managed similarly to patients with typical KD. Abnormal laboratory findings are of critical importance in making this diagnosis.

CRITICAL INTERVENTIONS

- Order a baseline electrocardiogram to assess for evidence of myocarditis or pericarditis.
- Recognize that the diagnosis of KD may be based entirely on clinical presentation.
- Ensure timely initiation of high-dose IVIG and aspirin therapy.
- Perform a full fever evaluation even if it is suspected that fever is caused by KD.

DISPOSITION

Children with a presumptive diagnosis of KD or incomplete KD should ideally be admitted to a tertiary care pediatric center where pediatric cardiologists and infectious disease consultants are

available. Transfer to a pediatric intensive care unit should be considered for patients with signs of cardiac decompensation.

Common Pitfalls

- Failure to consider KD in the differential diagnosis of prolonged fever in young children
- Failure to consider incomplete KD in prolonged fever in infants and young children
- Failure to monitor for or identify cardiac decompensation
- Failure to use laboratory screening tests, such as ESR, to help differentiate KD from common childhood viral exanthems
- Failure to recognize the importance of early admission, institution of therapeutic interventions such as IVIG and aspirin, and cardiology consultation

CHAPTER 277 Cellulitis

Robert L. Cloutier

Cellulitis is a common, acute, rapidly spreading, nonsuppurative inflammation of the epidermis, dermis, and subcutaneous fat that is usually caused by bacterial infection. The age of the patient, the history, and the location of the infection all serve as important determinants of the most likely causative bacterial organisms. Cellulitis may occur by local tissue invasion after minor traumatic skin breaks and bite wounds or by hematogenous dissemination of a pathogenic organism. It may also be the presenting sign of disease states such as septic arthritis, osteomyelitis, sinusitis, or pyomyositis (1). Neonatal omphalitis (infection of the umbilical stump and surrounding tissues) and neonatal mastoiditis are unique to the newborn period.

Recent studies have demonstrated a dramatic increase in the incidence of soft-tissue infections in the United States and concomitant emergency department visits (2). These increasing infection rates are due to the emergence of community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA), which affect otherwise healthy children (3,4). Most of the culture-proven CA-MRSA infections present as superficial abscesses or and carbuncles.

In most instances, children with cellulitis recover uneventfully. However, the recent resurgence of invasive group A β-hemolytic *Streptococcus* (GABHS) infection, characterized by bacteremia, toxic shock, and necrotizing fasciitis, emphasizes both the potential for serious complications and the need for accurate diagnosis and appropriate management of pediatric cellulitis.

EPIDEMIOLOGY

During the course of normal play, children routinely incur minor injuries with breaks of the skin. Any injury or skin opening that disrupts the protective barrier of the skin can serve as a portal of entry for pathogens, most commonly GABHS or *Staph aureus.* The role of MRSA in cellulitis without obvious purulence is unclear because cultures are rarely obtained from children with these infections, but CA-MRSA has emerged as an increasing cause of purulent soft-tissue infections in children (4). The incidence and prevalence of CA-MRSA vary geographically. In surveillance conducted in areas of Maryland, Georgia, and Minnesota in 2001 and 2002, the proportion of all MRSA infections that were caused by CA-MRSA ranged from 8% to 20% (4). Factors common in outbreaks of CA-MRSA include crowding; frequent skin-to-skin contact between people; participation in activities that result in abraded or compromised skin surfaces; sharing of potentially contaminated personal items such as towels, sporting equipment, and razors; and limited access to health care. One explanation for these increased infection rates is related to virulence characteristics that are more common in this organism. One such factor is thought to be a cytotoxin, Panton-Valentine leukocidin, that destroys leukocytes by creating pores in the cell membranes. CA-MRSA should be considered a potential cause of every infection presenting to the hospital or clinic, emphasizing the need for practitioners to be aware of local antibiotic resistance patterns.

Puncture wounds by a contaminated object such as a nail penetrating a shoe may predispose to infections with pathogens such as *Pseudomonas* species. Likewise, animal and human bites are associated with an increased likelihood of *Pasteurella multocida* and *Eikenella corrodens* infections, respectively.

Omphalitis, infection of the umbilicus, with accompanying erythema of the abdomen, is a diagnosis unique to the newborn period that usually occurs in the first few weeks of life. Neonatal mastitis is an infection of the breast tissue in prepubertal children, limited to the first 2 to 5 weeks of life (5). Female infants are

affected twice as often as males. Hormonally induced hypertrophy of the glandular tissue facilitates bacterial entry and abscess formation. The most common pathogen is *Staph. aureus,* including CA-MRSA; however, occasionally gram-negative enteric organisms are involved.

The epidemiology of childhood facial cellulitis has changed dramatically since the introduction of the *Haemophilus influenzae* type B vaccine in 1985. *H. influenzae* type B (HIB) had been the cause of more than 50% of cases of facial cellulitis but, in the post-vaccine era, it has become rare. In fact, there has been an approximately 90% decrease in the incidence of HIB disease (6). Any child who has received the second dose of HIB vaccine more than 7 days prior is unlikely to have HIB disease. Currently, common organisms for facial cellulitis include *Streptococcus pneumoniae,* GABHS, and *Staph. aureus.* As more children become completely immunized with the conjugated pneumococcal vaccine it is anticipated there will be a decrease in cellulitis due to *Strep. pneumoniae* vaccine and nonvaccine serotypes. Facial and periorbital infections caused by HIB and *Strep. pneumoniae* are usually spread hematogenously and hence can be isolated by blood cultures. Primary dental infection may also lead to bacterial seeding of adjacent facial soft tissues by a variety of aerobic and anaerobic bacteria such as *Bacteroides, Prevotella, Fusobacterium,* and *Peptostreptococcus* (7).

Important pre-existing conditions that may predispose to cellulitis include other traumatic injuries, particularly crush injuries, pre-existing vascular or lymphatic compromise, chronic cutaneous conditions such as eczema, and immunocompromised states. More recently, there has been an increase in case reports of necrotizing fasciitis due to GABHS infection occurring in conjunction with varicella infection (8).

CLINICAL PRESENTATION

The most reliable way to diagnose cellulitis is to recognize the characteristic clinical features: Localized erythema, warmth, edema,

and pain. Demarcation between involved and adjacent normal skin may be indistinct. Most often, cellulitis involves the extremities, with the leg affected three times as often as the arm (1). There may be associated lymphangitis, appearing as red streaks radiating from the margin of the lesion, and also enlargement and tenderness of regional lymph nodes, particularly with streptococcal infection. The white blood cell (WBC) count is usually normal. In 10% to 20% of cases, cellulitis is associated with fever and other systemic symptoms such as chills, malaise, myalgias, and emesis. When fever is present, a concomitant bacteremia should be presumed leukocytosis is expected.

More recently, increasing childhood purulent infection rates due to CA-MRSA, and the inability to distinguish these infection from methicillin-sensitive strains, have necessitated the development of new evaluation and management schemata for these infections, such as that recommended by the American Academy of Pediatrics (Fig. 277.1) (9).

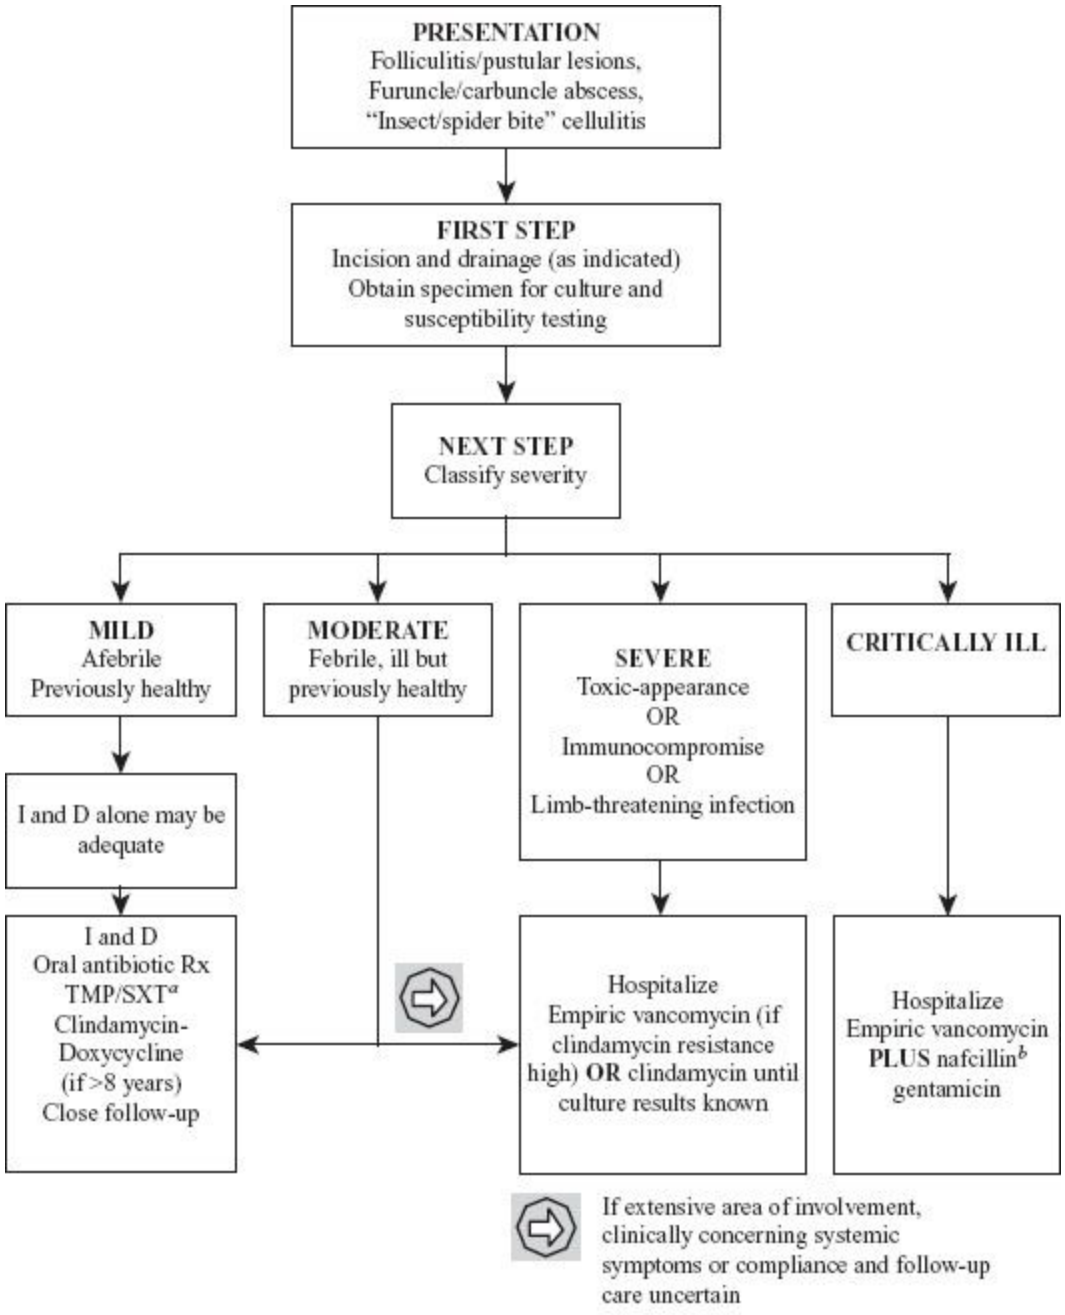

FIGURE 277.1 Initial outpatient management of suspected CA-MRSA skin and soft-tissue infections schematically illustrated. Assumes CA-MRSA strains are prevalent in a community.

Erysipelas is a superficial cellulitis predominantly affecting the upper dermis. It is characterized by tender, rapidly enlarging,

erythematous, indurated plaques with sharply demarcated borders, with extensive lymphatic involvement. Patients tend to be young children, and most cases involve the legs and feet (10,11). Symptoms also include toxic appearance with fever and chills (12). Facial erysipelas may occur after streptococcal upper respiratory tract infection (10). GABHS is the most common cause of erysipelas, in addition to other streptococcal groups including groups B, C, and G. Historically, erysipelas has rarely been linked to staphylococci. Current investigations still acknowledge the possibility of CA-MRSA as a causative agent but data supporting its existence remains weak (13).

Buccal cellulitis presents as a tender mildly erythematous swelling of the cheek in children between 6 and 24 months, most often not associated with previous trauma. Hematogenous seeding by oropharyngeal or middle-ear bacteria is suggested as the pathogenesis (6). Previously, HIB was by far the most common etiologic agent, with rare cases caused by *Staph. aureus* and *Strep. pneumoniae.* As a result of routine immunization with HIB vaccine, the incidence of buccal cellulitis has decreased (12). Of note, in infants younger than 3 months of age, facial cellulitis may be the only presenting sign of GBS bacteremia.

Ludwig angina is a cellulitis of the submandibular and sublingual space. Patients often present with rapidly progressive, tense, and painful induration of the submental area and neck, along with drooling, dysphonia, high fever, and leukocytosis. It is important to recognize the potential for airway compromise in such patients (12). Predisposing factors include poor dental hygiene, recent dental extractions, and impacted foreign bodies in the oral cavity. Infections tend to be polymicrobial, involving oral flora.

Periorbital or preseptal cellulitis is an infection presented anterior to the orbital septum and is usually seen in children younger than 5 years old (6,14). It typically presents with sudden onset of unilateral eyelid and periorbital tenderness, swelling, and erythema; extraocular eye movements and visual acuity are preserved and there is no evidence of proptosis (12). More than half cases are secondary to local extension from a nearby facial wound infected

with either GABHS or *Staph. aureus*. In general, children appear nontoxic, but bacteremia and leukocytosis may occur, particularly when infection is due to *H. influenzae* or *Strep. pneumoniae* infections.

In contrast, *orbital cellulitis,* which is less common than periorbital cellulitis, is postseptal and involves the orbit itself (14) (see Chapter 253). Ethmoid sinusitis is most commonly the source of infection as the ethmoid sinus is separated from the orbit by the rather thin bony structure known as the *lamina papyracea* (14).

Omphalitis presents in the newborn as purulent, foul-smelling discharge from the umbilical stump and as erythema of the abdominal wall. However, both of these clinical findings may occur without infection, thus making the diagnosis challenging at times. Suggestive findings include anterior abdominal erythema and circumferential erythema of the umbilicus (5). The cord stump may serve as a portal of entry for *Staph. aureus,* CA-MRSA, GABHS, group B *Streptococci* (GBS), or gram-negative enteric organisms. Infection is clinically diagnosed when induration and erythema of the anterior abdominal wall are present. Fever, temperature instability, lethargy, and irritability may be seen late as signs of sepsis. Laboratory studies such as WBC count may be normal in early localized infections. Omphalitis is rare in developed countries where the usual cord care in the neonatal period avoids most infections.

Neonatal mastitis presents as enlargement of the breast bud with associated tenderness, warmth, erythema, and purulent nipple discharge (5). Hormonally induced hypertrophy of the breast tissue does not present as erythema or tenderness and is associated only with a milky white discharge. About one-fourth of infants will present with fever and ill appearance. Since the infection tends to be well localized, the WBC is normal in most cases, and blood cultures are negative.

Wound-related cellulitis is the most common cause, of cellulitis of the extremities, especially in older children and adolescents (12). The involved area is red, warm, and tender, and systemic signs of fever, chills, and leukocytosis are often present. Lymphangitic streaking and regional lymphadenopathy are more common than in

cases of erysipelas. Children with cellulitis of an extremity may have limitation of movement of the affected limb or refusal to walk because of pain. Infections tend to be polymicrobial and are age related, with GBS more common in infants younger than 3 months old, *Strep. pneumoniae* and HIB in patients aged 6 to 24 months (still undergoing primary vaccination series), and *Staph. aureus,* CA-MRSA, and GABHS most likely in children older than 24 months (1). With GBS, *Strep. pneumoniae,* and HIB, high fever, WBC above 15,000, and bacteremia are not uncommon.

Necrotizing fasciitis (NF) is an uncommon but potentially devastating infection of the subcutaneous and fascial tissues (11). Children may be predisposed as a result of traumatic skin lesions, or those of varicella zoster infection, eczema, or burns (12,15,16). Necrotizing fasciitis may initially present as a cellulitis, but develops rapidly into dusky, painful, indurated plaques and progresses to purpura, blistering, and necrosis. Crepitance may develop within the tissues. The infection spreads rapidly along fascial planes between subcutaneous tissue and superficial muscle fascia (15). The initial diagnosis may be difficult to make because there are often only modest skin changes early in the course of disease. However, extreme pain that is out of proportion to examination findings is very suggestive. Patients may present with fever and marked fussiness and may refuse to bear weight or move the affected limb. Severe systemic toxicity with tachycardia, hypotension, and multiorgan system failure are common in fulminant cases. The child may be lethargic, disoriented, and in profound septic shock. When necrotizing fasciitis occurs in conjunction with streptococcal toxic shock syndrome (STSS), the mortality rate is particularly high (15).

STSS may be associated with NF in as many as 50% of cases (10). The syndrome presents with a generalized, fine, scarlatiniform rash and hyperemia of the conjunctivae or other mucous membranes, along with fever, tachycardia that out of proportion to fever, hypotension, and possibly altered mental status and respiratory distress, vomiting, diarrhea, and renal and hepatic dysfunction are often present (10,15).

A similar toxin-mediated syndrome affecting young children is *staphylococcal scalded skin syndrome* (SSSS). Skin manifestations are age related and include the spectrum of bullous impetigo, scarlatiniform eruption, and widespread exfoliation (11). Generalized SSSS, called *Ritter disease,* usually occurs in patients younger than 5 years of age; older children tend to have more localized infections. Following a purulent conjunctivitis, upper respiratory infection, or localized superficial skin infection, a generalized orange-red macular erythema resembling sunburn develops. During the subsequent scarlatiniform phase, the skin becomes extremely tender. Within 1 to 3 days, the skin becomes wrinkled, and large flaccid bullae develop in flexural areas or around orifices. During this phase, Nikolsky sign is present—the epidermis pulls away from the dermis with gentle traction, leaving raw, weeping, and denuded skin underneath (12). As the skin dries, large flakes are formed, leading to widespread desquamation with complete recovery in 10 to 14 days. Dehydration and superinfection may occur due to loss of the dermal barrier during exfoliation.

DIFFERENTIAL DIAGNOSIS

Any tender, erythematous swelling of the skin and subcutaneous soft tissue may resemble cellulitis. Trauma, insect bites or stings, localized urticarial eruptions, lymphadenitis, swelling overlying a sprain or fracture, or a joint with septic arthritis may all be mistaken for cellulitis. Mosquito bites may induce significant lymphedema surrounding the bite site, which develops over hours. The bites are usually described as pruritic rather than painful. Bee stings and spider bites may also cause significant lymphedema, warmth, and even tenderness and therefore may be more difficult to distinguish from cellulitis.

"Popsicle panniculitis" can mimic facial cellulitis. Thought to be a cold-induced histamine response from drinking ice water, typically the skin involvement begins at the labial crease and spreads outward with a warm, mildly tender cheek. Insect bites and stings,

panniculitis, and orthopedic injuries all lack accompanying systemic signs such as fever or ill appearance.

Localized specific soft-tissue infections, such as folliculitis (infection of a hair follicle), furuncles and carbuncles (deep follicular abscess, either solitary or multiseptate and loculated), impetigo (vesiculopustular lesions), ecthyma (impetigo involving the dermis), and others, should be differentiated from cellulitis by their characteristic clinical appearances.

Extremity cellulitis, as mentioned earlier, may limit range of motion of the affected limb; making it difficult to distinguish deeper tissue infections (such as osteomyelitis or septic arthritis) from cellulitis.

ED EVALUATION

In most cases, cellulitis is a clinical diagnosis. Blood culture and WBC counts should be reserved for immunocompromised patients or those presenting with fever or other signs of systemic illness. Clinical judgment and patient age should be used to determine the need for lumbar puncture for culture, particularly with cellulitic infections of the head and neck region (6). In infants with facial cellulitis who have not been fully immunized a lumbar puncture should be strongly considered (6).

Many clinical features are specific enough for clinical decisions to be made based on appearance alone; however, given the rapid increase in frequency of CA-MRSA, cultures may become more necessary. Erysipelas, with its characteristic rapidly advancing, raised, sharply demarcated margin, is usually caused by GABHS. A bluish or violaceous discoloration of the affected area suggests infection by *H. influenzae* or *Strep. pneumoniae.* Cellulitis in the perineal or buccal area, or cellulitis in an area involving devitalized or necrotic tissue should raise concern for polymicrobial anaerobic organisms or CA-MRSA. Cellulitis caused by pet bites is often associated with *P. multocida,* whereas human bite infections are often associated with *E. corodens.* Cellulitis due to water-contaminated wounds is usually caused by *Mycobacterium marinum*

or *Aeromonas* and *Vibrio* species (17). Systemic symptoms in any patient with cellulitis should suggest the possibility of concurrent bacteremia. Immunocompromised states should alert the clinician to the possibility of atypical infectious agents and to neutropenia potentially masking the actual depth and extent of infection.

While varicella is relatively rare because of routine immunizations against it, invasive GABHS should be considered in children with varicella who have fever on or beyond the fourth day of the exanthem (8). With the re-emergence of suppurative GABHS infections, it is vital to distinguish early streptococcal necrotizing fasciitis from cellulitis. Although the combination of clinical features and epidemiologic considerations may suggest the etiology of cellulitis, definitive bacteriologic diagnosis requires isolation of the causative organism. In the past, because of the high prevalence of *H. influenzae,* bacteremia, blood cultures were routinely obtained in children with cellulitis. In the post-HIB vaccine era, however, the association of bacteremia with cellulitis in children has been dramatically reduced, and recent studies indicate that it is not necessary to obtain blood cultures routinely (18). Of note, positive blood cultures are most commonly associated with younger age, active varicella, and deeper tissue infections such as osteomyelitis or septic arthritis.

Needle aspiration of the cutaneous lesion, accompanied by gram stain and culture, is a rapid and specific tool for establishing a bacteriologic diagnosis. Aspiration is performed by inserting a 22-gauge needle attached to a 1-cc syringe into the advancing edge of the cellulitis. If no material is aspirated, 0.1 mL of normal saline may be injected into the area, followed by immediate aspiration. The yield of needle aspiration, however, can be modest; positive aspiration rates vary from 5% to 50%.

If underlying deeper trauma or infection is suspected, appropriate imaging should be ordered, especially in patients with suspected orbital cellulitis (19). Patients with cellulitis involving the midface are also susceptible to cavernous sinus thrombosis.

Complications of cellulitis may result from direct extension, seeding of an underlying joint space, or hematogenous spread.

Meningitis, endocarditis, or other serious complications, although rare, may develop, especially in immunocompromised patients.

KEY TESTING

- CBC, blood culture, and wound cultures in patients with atypical presentations, ill appearance, or immunocompromise
- CT scan for patients with suspected orbital cellulitis
- CT, MRI, or ultrasonography to investigate potential joint infections or osteomyelitis

ED MANAGEMENT

Antibiotic therapy is warranted in most cases, except in the mildest forms of cellulitis. See Figure 277.1 for management of purulent infections (9). Given the low yield of microbiologic testing, in most situations antibiotic therapy is empiric but should be based on sound clinical judgment.

The presence of pus should prompt a high index of suspicion for CA-MRSA, and incision and drainage with packing should be performed. Any fluid aspirated should be cultured, including MRSA typing. Hospital admission and parenteral antibiotic therapy should be strongly considered in any febrile child. Application of warm compresses and elevation of the affected limb are useful adjunctive therapies. Analgesics may be necessary for pain control, and antipyretics for relief of fever.

All neonates with suspected omphalitis or mastitis should be promptly admitted and started empirically on parenteral antibiotics for *Staph. aureus* and CA-MRSA, GABHS, GBS, and gram-negative enteric organisms. In infants younger than 3 months of age with facial or extremity cellulitis should be admitted and treated with parenteral penicillin and an aminoglycoside. Between 3 months and 3 years of age, *Staph. aureus, H. influenzae,* or *Strep. pneumoniae* may be causative organisms, and third-generation cephalosporins (ceftriaxone or cefotaxime) should be administered, as well as clindamycin. In ill-appearing children, clinicians should consider the possibility of a more invasive infection and have an increased

suspicion for CA-MRSA (16). Vancomycin is required if meningitis is suspected.

Patients with orbital cellulitis require hospital admission. Multispecialty involvement by otorhinolaryngology, infectious diseases, and ophthalmology is warranted, since surgical drainage of an abscess or a sinuses may be required. Patients should be started empirically on intravenous antibiotics to cover respiratory pathogens; ampicillin–sulbactam is a reasonable choice (14). Intravenous antibiotics for a total of 7 days, followed by a course of oral antibiotics for 14 days, are recommended.

Patients suspected of a severe infection with GABHS should receive parenteral clindamycin in addition to penicillin, intravenous immunoglobulin, an immediate surgical consultation for emergent débridement, and close cardiorespiratory monitoring for signs of septic shock. Aggressive fluid resuscitation may be required. Surgical intervention must not be delayed by radiologic investigations when the clinical likelihood of sever disease is high (10,15,16).

Immunocompromised patients often develop cellulitis caused by atypical organisms such as *Corynebacterium, Pseudomonas,* atypical mycobacteria, and even fungi. A microbiologic diagnosis should be vigorously pursued in these patients, particularly when initial empirical therapy fails to produce a satisfactory response.

Beyond 3 years of age, patients with well-localized cellulitis and without fever or systemic illness may be treated as outpatients with antistaphylococcal and anti-GABHS oral agents. Consider the addition of anaerobic coverage with clindamycin for cases of bite wounds, oral infections, or wounds with devitalized tissue. Caregivers of children who are treated as outpatients require instruction about the necessity of close follow-up within 48 hours and about signs and symptoms that necessitate prompt return to the ED.

Susceptibility patterns of CA-MRSA to clindamycin and trimethoprim–sulfamethoxazole differ in various regions of the country. Generally, either of these agents can be used to treat mild-to-moderate cellulitis due to such MRSA. In the case of severe

infection with CA-MRSA, empiric, parenteral vancomycin is recommended (20).

A patient with cellulitis who shows severe systemic toxicity or does not improve within 48 hours of oral antibiotic therapy should receive high-dose intravenous broad-spectrum antibiotic therapy covering both streptococci and staphylococci. Newer recommendations favor changing empiric therapy to include CA-MRSA coverage. Antibiotic recommendations for possible CA-MRSA infection are presented in Table 277.1.

TABLE 277.1
Antibiotic Doses for the Treatment of Infections Caused by CA-MRSA

Antibiotic	Daily Dose (mg/kg/day)	Interval (H)
Vancomycin	40–60 (IV)	6–8
Clindamycin	30–40 (IV or PO)	8
Gentamicin[a]	3 (IV)	8
Rifampin[a]	20 (IV)	12
Trimethoprim–sulfamethoxazole	10–12 (IV or PO)	12
Linezolid	30 (IV or PO)	8 for children <12 year
	20 (IV or PO)	12 for children >12 year
Minocycline[b]	100 (PO)	12

[a]Used for synergy in combination with vancomycin; not used alone.
[b]For children older than 8 years of age; represents total dose, not per kilogram.

Patients who respond promptly to parenteral antibiotics may be switched over to oral antibiotics but in most cases the total duration of therapy should be a full 10 days.

CRITICAL INTERVENTIONS

- Recognize that patients with necrotizing fasciitis present with pain out of proportion to physical examination findings.
- Arrange follow-up within 48 hours for patients with cellulitis who are treated on an outpatient basis.
- Recognize that patients with purulent infections should be cultured and treated as if they have CA-MRSA.

- Recognize that mastitis and omphalitis are serious forms of cellulitis in the neonatal period that mandate emergent evaluation and treatment.

DISPOSITION

Most children with simple cellulitis can be started on oral antibiotics on an outpatient basis, with follow-up arranged at 48-hour intervals. With the decreasing incidence of *H. influenzae* and *Strep. pneumoniae* cellulitis and the availability of potent oral antibiotics, more and more patients with cellulitis can be safely managed as outpatients.

Admission should be strongly considered in infants younger than 6 months old. Any child, who appears to be ill, has extensive lesions or is immunosuppressed should also be admitted. Patients with facial cellulitis and a fever of $>38.5^{\circ}C$ or those with extremity cellulitis and a fever of $>39^{\circ}C$ and a WBC count $>15{,}000/mL$ are likely to require intravenous antibiotics.

Patients with necrotizing fasciitis require surgical débridement in the operating room. Children with severe systemic manifestations need aggressive treatment and admission to a pediatric intensive care unit. Wound management in cases of extensive SSSS may be best accomplished in a pediatric burn unit.

Common Pitfalls

- Failure to recognize that CA-MRSA infection in children without identified risk factors is increasing in prevalence
- Failure to include orbital cellulitis in the differential diagnosis of periorbital cellulitis
- Failure to recognize that in immunocompromised patients with cellulitis, atypical and opportunistic infections are common and that a microbiologic diagnosis should be actively pursued

CHAPTER 278 Meningitis and Encephalitis

James A. Wilde

Central nervous system (CNS) infections are a source of significant morbidity and mortality and are often considered in the differential diagnosis of a febrile child. Bacterial meningitis and viral disease presenting as meningitis, encephalitis, or meningoencephalitis are the most common forms of CNS infection in children. Because of their low prevalence and often subtle presenting signs and symptoms and because of the overwhelming nature of CNS infections, these diseases present a formidable challenge to emergency physicians, both diagnostically and therapeutically.

The organisms most commonly isolated in cases of bacterial meningitis vary with the age of the patient. Among neonates, group B *Streptococcus* (GBS) is by far the most commonly isolated bacterium. Other less common but significant organisms include *Listeria monocytogenes* and gram-negative enteric bacilli such as *Escherichia coli, Klebsiella* and *Enterobacter* species, *Citrobacter diversus,* and *Salmonella* species. GBS and *L. monocytogenes* typically present as "late-onset" meningitis at 1 to 12 weeks of life, whereas meningitis caused by the gram-negative enteric bacteria often presents during the first 2 weeks. Beyond the age of 3 months, *Streptococcus pneumoniae* and *Neisseria meningitidis* are the major pathogens, with *S. pneumoniae* predominating from 2 months to 10 years and *N. meningitidis* predominating from 11 to 17 years. Meningitis caused by *Haemophilus influenzae* type B (HIB) is now rare in the United States owing to a highly effective vaccine (1).

The leading pathogens caused an estimated 1,400 cases of bacterial meningitis in US children younger than 18 years in 2007 (1). This represents a dramatic decline associated with the near-eradication of HIB meningitis following the introduction of Hib conjugate vaccine in 1990. Two-thirds of patients with bacterial meningitis in 1986 were between 1 month and 5 years of age, but by 1995 meningitis in this age group had dropped by 87%, and the median age of bacterial meningitis cases rose from 15 months to 25 years. A second sharp decline in bacterial meningitis was noted with the introduction of the pneumococcal conjugate vaccine in 2000.

Bacterial meningitis is almost always preceded by a hematogenous spread of bacteria. The mechanism whereby bacteria gain access to the intravascular space is unclear, although some data suggest that viral upper respiratory infections may cause a breach of the normal mucosal barriers. It is also unclear how bacteria, once in the bloodstream, gain access to the CNS. Bacterial meningitis can also result from direct invasion of the CNS after trauma or erosion through an infected sinus, but this is a much less common mechanism.

Most instances of bacteremia do not progress to invasion of the CNS. However, once in the CNS, bacteria can initially multiply relatively unimpeded because of the poor immunologic defenses within normal cerebrospinal fluid (CSF) (2). It is only after local release of bacteria-associated chemotactic factors that the CNS mounts a significant defense. The resulting inflammation, edema, and CNS dysfunction are seen clinically as severe headache, nuchal rigidity, photophobia, or seizures. A patient with fever can be anywhere on this continuum but, without CSF for evaluation, it is generally not possible to state definitively when or if the child has reached the meningitic stage.

Aseptic meningitis (i.e., meningitis without the evidence of a bacterial pathogen in the CSF) may be caused by a number of infectious or noninfectious agents. Enteroviruses (ECHO and coxsackievirus) and the mumps virus are among the most common infectious etiologies. Encephalitis is an inflammation of the brain that can occur as a primary pathologic event, as in arbovirus

encephalitis, or as a simultaneous event with primary meningitis. The latter is more correctly termed *meningoencephalitis* and is common in bacterial meningitis. Among the many viral causes of encephalitis are the enteroviruses, arboviruses (West Nile virus, La Crosse strain of the California encephalitis virus [CEV], St. Louis encephalitis), herpes simplex virus (HSV), varicella virus, and mumps virus. Infections caused by enteroviruses and arboviruses occur primarily during the warmer months, with the arbovirus infections paralleling mosquito activity. Infection by CEV is typically seen in young boys exposed to hardwood forests or small pools of stagnant water, where mosquitoes breed (3). HSV encephalitis can occur at any age, including a neonatal form that presents during the second to third week of life.

CLINICAL PRESENTATION

Owing to the protean clinical manifestations of bacterial meningitis in infants and young children, physicians must maintain a high index of suspicion for the disease. Inflammation of the meninges can be manifested by headache, nausea and vomiting, fever, photophobia, mental confusion and lethargy, or excessive irritability, none of which are specific for meningitis. Other clinical findings that are suggestive of meningitis include seizures, focal neurologic signs (hemiparesis, quadriparesis, cranial nerve palsies, visual-field defects), and ataxia, though no single sign is pathognomonic. The symptoms and signs of meningitis vary and depend in part on the patient's age, the duration of illness, and the host's response to the infection. Clinical findings, especially in neonates and young children, may be subtle and nonspecific, including disinterest in feeding, lethargy, respiratory distress, or jaundice. *Fever is commonly absent in neonates with bacterial meningitis.*

A change in the child's affect or state of alertness is one of the most important signs of bacterial meningitis. In one study, depending on the patient's age, 36% to 60% of meningitic children were described as toxic or moribund, and 73% to 100% as lethargic or comatose (4). Interestingly, these findings were generally not present in infants younger than 3 months. *Lethargy* refers to a decreased level

of consciousness with an inappropriate response to stimuli bordering on unconsciousness. However, a child who is sleepy is not necessarily lethargic. Likewise, a febrile child who is playful, smiling, and interactive is unlikely to have bacterial meningitis in the absence of other suggestive signs or symptoms.

Seizures are noted at presentation in 20% to 30% of children with bacterial meningitis (5). *Seizures are rarely the sole manifestation of meningitis in febrile children.* Most children with seizures secondary to bacterial meningitis have a significant, prolonged alteration in their level of consciousness or focal findings on physical examination (6). This is in marked contrast to children with simple febrile seizures who, after a short postictal period, usually return quickly to their baseline mental status and have no neurologic deficits on examination.

Bacterial meningitis in infants and children can present either insidiously over several days or acutely and fulminantly over several hours. The prognosis may be worse for the second group (7), who are not generally not difficult to recognize at presentation. Despite physicians' best efforts, delays in diagnosis are common in those with more insidious presentations. It is unclear whether these delays contribute to subsequent morbidity or mortality (8,9).

Enteroviral infection is typically insidious in onset and may have a biphasic course extending over 10 days or more. Furthermore, the patient with enteroviral meningitis does not usually appear seriously ill unless the infection occurs during the neonatal period.

Differentiating HSV infection from bacterial meningitis may be difficult because the nonspecific symptoms just described are found in both infections. Helpful clues include the absence of bacteria on CSF Gram stain, negative cultures of blood and CSF, the presence of focal seizures, and difficult-to-control seizures. Cutaneous vesicles are found at presentation in only 30% to 50% of infants with neonatal HSV and are uncommon at any stage of HSV encephalitis in older children. St. Louis encephalitis and La Crosse encephalitis can present either in a mild form, consisting of a 2- to 3-day prodrome of low-grade fever, headache, malaise, and vomiting with subsequent development of higher fever, lethargy, and meningeal signs, or in a

severe form, characterized by the abrupt onset of fever and headache followed rapidly by generalized or focal seizures, focal neurologic signs, and coma. HSV encephalitis in the older child may be similar to this severe form of arboviral encephalitis.

An altered state of consciousness is apparent in most children with encephalitis owing to inflammation of the brain parenchyma. This may be manifested by lethargy or delirium, but in severe cases lethargy may progress to a stuporous state or frank coma.

DIFFERENTIAL DIAGNOSIS

While not always apparent at presentation, nuchal rigidity is the clinical sign physicians most associate with meningitis. It is, however, associated with a wide variety of illnesses including:

- *Infections:* Meningitis, encephalitis, brain abscess, epidural abscess, Guillain–Barré syndrome, transverse myelitis, acute cerebellar ataxia, poliomyelitis, tetanus, cervical adenitis, retropharyngeal abscess, vertebral body osteomyelitis, discitis, epiglottitis, trichinosis, tonsillitis, otitis media, pyelonephritis, mumps, hepatitis, shigellosis, malaria, typhoid fever.
- *Vascular abnormalities:* Subarachnoid hemorrhage, intracranial venous thrombosis.
- *Neoplasms:* Meningeal leukemia, intracranial and brainstem tumors, tumors of the cervical vertebrae (osteoid osteoma, eosinophilic granuloma).
- *Metabolic disorders:* Infantile Gaucher disease, maple syrup urine disease, kernicterus.
- *Bony or muscular disorders:* Vertebral anomalies; subluxations, dislocations, and fractures of the cervical spine; myositis; fibromyositis; congenital torticollis.

Children with common, self-limited viral infections may present with symptoms that mimic meningitis. Headache, somnolence, and decreased activity are common symptoms in many childhood infectious diseases. Children with these non-CNS infections may appear toxic on initial presentation but often become alert and playful if the fever responds to antipyretics. *Symptoms of bacterial meningitis generally do not abate with antipyretics alone.*

ED EVALUATION

A careful history can help to differentiate a child with a serious systemic bacterial infection such as sepsis or meningitis from one with a self-limited viral infection. It is important to note that the overwhelming majority of children with fever do not have bacterial meningitis, which is now a rare disease. If each child between 2 months and 2 years of age had only one febrile illness per year of life, the expected rate of bacterial meningitis would be <1 case per 14,000 febrile episodes. Most children in this age group have more than one febrile illness per year, so the actual rate is much lower. Information gathered from the history and physical examination can help the physician to decide who requires LP for further evaluation (Table 278.1).

TABLE 278.1
Indications for Lumbar Puncture and/or Immediate Empiric Treatment for Meningitis

Recommended	Strongly Consider
Unexplained fever and:	Unexplained fever and:
Lethargy	Seizure in child <18 months or >5 year of age
Coma	Severe headache
Shock	No obvious source for fever, child <3 month of age
Extreme irritability in infant	Poor feeding in infant
Age <1 month	Increased sleep in infant
New neurologic deficit	Petechial or purpuric rash
Nuchal rigidity	Any afebrile, toxic-appearing child with symptoms from either column
Photophobia	
Uncontrolled seizure	
Seizure in child <6 months of age	
New-onset focal seizure	

Bacterial meningitis leads to inflammation of the brain and meninges, which causes symptoms such as extreme irritability, photophobia, vomiting, headache, lethargy, and seizures. Excessive

sleep or poor feeding may be observed in infants. The emergency physician should initially focus on these elements of the history in the assessment of a febrile child. Their absence does not rule out meningitis but does make it less likely. Conversely, their presence should heighten suspicion for meningitis.

In addition, questions should be directed toward establishing a source for the fever. Are there any ill contacts with fever? Are there signs or symptoms that are temporally related to the fever and that together constitute a self-limited viral illness? Prior or current antibiotic administration is another important historic item to ascertain.

In the evaluation of a neonate with fever, the mother should be questioned about infections during pregnancy or at delivery. The physician should ask about pruritic or burning vaginal lesions, antibiotic use during pregnancy, ingestion of raw dairy products during pregnancy (listeriosis), parental history of or exposure to HSV, perinatal complications in the mother or child, prolonged care in the nursery after delivery, the mother's GBS status at the time of delivery, and any antibiotic use in the child since birth.

In all febrile children, a history of exposure to someone with sepsis or meningitis should be sought. Travel history and animal contact are important factors to consider when dealing with the less common causes of CNS infections. Mosquito bites may suggest an arbovirus infection.

Parents tend to use the word *lethargic* to describe their children when, in fact, true lethargy is not present. A child who is less playful or more sleepy than usual is not necessarily a lethargic child. Decreased play and increased sleep are almost universally present in young children with febrile illnesses.

A complete physical examination is critical in the evaluation of a febrile child to detect a CNS infection or to establish a reasonable alternative explanation for fever. The following are important questions to ask: Does the child have signs of an acute upper respiratory infection? Does the child have an obvious pharyngitis or oral lesions consistent with herpangina or herpetic gingivostomatitis? Is there a rash consistent with a clear etiology, such as varicella or

the sandpaper rash of scarlet fever? Does the child have conjunctivitis or otitis? Hypotension or prolonged capillary refill time in the absence of dehydration suggests a potentially life-threatening bacterial infection.

The chest, abdomen, and extremities should be examined to search for the evidence of serious bacterial infections such as pneumonia, peritonitis, pyelonephritis, septic arthritis, cellulitis, or osteomyelitis. Look for the presence of a bulging anterior fontanelle in infants in the seated position, an indication of increased intracranial pressure (ICP). Although the funduscopic examination is usually normal in acute CNS infections, the presence of papilledema should raise concern for a brain abscess, subdural empyema, or venous sinus thrombosis. A complete neurologic examination is important to determine the presence and severity of a CNS insult and to document a baseline against which the response to therapy can be monitored.

In all patients with suspected CNS infection, signs of meningeal irritation are sought by examining for nuchal rigidity and Kernig and Brudzinski signs. Especially in a very young child who is frightened by the ED setting, forceful flexion of the neck can be misleading, because the child's natural tendency is to resist the examiner. A toy or flashlight placed at the sitting child's umbilicus usually causes the child to flex the neck spontaneously and may be more helpful in excluding nuchal rigidity. Kernig sign is positive when pain is elicited by extension of the knee from its initial flexed position, with the patient supine and the leg flexed at the hip. The Brudzinski sign consists of spontaneous flexion of the lower extremities after passive flexion of the neck. Meningeal signs are almost invariably present at the time of diagnosis in children older than 13 months with bacterial meningitis but are only rarely present in children younger than 6 months (10).

Careful attention to the child's affect or state of alertness is critical to distinguish those who should undergo LP for further evaluation from the vast majority who need no further invasive tests. The emergency physician should carefully document the general appearance of the child.

The definitive diagnosis of meningitis requires CSF analysis after performance of an LP. This procedure should include an opening pressure, if available, cellular analysis, glucose (including simultaneous serum glucose) and protein determinations, Gram-stained smear, and appropriate bacterial cultures. Viral, mycobacterial, and fungal cultures should be reserved for special circumstances and are not considered routine in otherwise healthy children.

The LP should be delayed if there are signs of significantly increased ICP, evidence of bacterial infection in or around the LP site, coma, focal seizures, new focal neurologic deficits, signs or a history of a bleeding disorder, or cardiopulmonary compromise. If the LP is to be delayed, blood cultures should be obtained and empiric antibiotics administered immediately; lifesaving therapy takes priority over diagnostic procedures.

The laboratory diagnosis of bacterial meningitis rests on demonstration of bacteria or inflammation in the CSF. Though early antibiotics may prevent the isolation of bacteria in subsequent CSF culture, obvious laboratory markers of inflammation persist for days to weeks in most cases. In addition, bacteria can be isolated from blood culture in up to 80% of patients with bacterial meningitis. The various rapid antigen diagnostic tests, including countercurrent immunoelectrophoresis, latex particle agglutination, and enzyme-linked immunosorbent assay, also may be helpful in establishing the etiologic agent if antibiotics have already sterilized the CSF.

A head computed tomography (CT) scan is not necessary before performance of LP (11) if the clinical scenario is consistent with uncomplicated meningitis or encephalitis. However, if the patient has focal neurologic findings, has signs of severely increased ICP, or is comatose (making neurologic examination unreliable), it is prudent to order a brain imaging study such as a contrast-enhanced CT to identify an abscess or other space-occupying lesion that might be considered a contraindication to performance of the LP.

The results of CSF analysis can give important clues to the etiology of the CNS infection **(Table 278.2).** However, in approximately 1% of cases of bacterial meningitis, CSF cell counts, glucose, and protein

are normal, and there are no organisms on Gram stain (12). A "normal" CSF profile thus does not completely rule out the possibility of bacterial meningitis, but it does render the diagnosis very unlikely. Viral infections of the CNS are typically associated with fewer than 500 white blood cells per microliter in the CSF and a lymphocytic predominance. CSF glucose and protein concentrations are usually normal. However, the initial CSF examination in a child with acute enterovirus meningitis may reveal a predominance of polymorphonuclear leukocytes, and the cell count may rarely exceed 1,000/μL.

TABLE 278.2
Typical CSF in Infants and Children

Component	Normal Children	Normal Newborn	Bacterial Meningitis	Viral Meningitis	Herpes Meningitis
Leukocytes/μL	0–6	0–30	>1,000	100–500	10–1,000
Neutrophils (%)	0	2–3	>50	<40	<50
Glucose (mg/dL)	40–80	32–121	<30	>30	>30
Protein (mg/dL)	20–30	19–149	>100	50–100	>75
Erythrocytes/μL	0–2	0–2	1–10	0–2	10–500

The values shown should be used only as a guide to diagnosis, because there is considerable overlap in CSF values for the different etiologic categories.
Source: Modified from Wubbel L, McCracken GH. Management of bacterial meningitis 1998. *Pediatr Rev.* 1998;19:78–84.

Interpretation of a traumatic tap is difficult, and previous recommendations for estimating the number of white cells on the basis of ratio of white to red cells in peripheral blood may be inaccurate (13).

In addition to blood culture and CSF analysis, the minimum laboratory evaluation should also include a complete blood count with differential and platelet count, coagulation studies if thrombocytopenia is present, serum electrolytes, urine sodium concentration, urinalysis, and, in some cases, a chest radiograph.

In suspected cases of encephalitis, helpful additional studies include viral cultures of CSF and mucosal surfaces, specific viral detection in CSF by polymerase chain reaction, electroencephalogram, and brain imaging studies (14).

KEY TESTING

- LP: Gram stain, protein, glucose, bacterial culture
- CBC with differential and platelet count
- Blood culture
- Serum electrolytes
- Urinalysis

ED MANAGEMENT

Supportive care and stabilization are of the utmost importance with CNS infections. Among the initial complications encountered are septic shock with its associated metabolic derangements, coagulopathy, intracranial hypertension, seizures, and hyponatremia resulting from the syndrome of inappropriate antidiuretic hormone (SIADH) secretion. The ED physician must be prepared to support the patient with acute meningitis and manage complications until an intensive care unit (ICU) setting can be arranged for definitive care.

Septic Shock

Simultaneous shock and cerebral edema present a theoretic therapeutic dilemma, because the treatment of one may adversely affect the other. Fluid resuscitation is an integral part of the management of septic shock, and treatment of systemic hypotension must take priority, often requiring massive amounts of crystalloid or colloid.. If there is no response after intravenous infusion of 40 to 60 mL/kg, pharmacologic support should be instituted with pressor agents such as dopamine. Patients who require this level of intervention should ideally be managed in an ICU setting, with a central venous pressure line, Foley catheter, and cardiorespiratory monitors.

Previous recommendations for the fluid management of children with meningitis have stressed fluid restriction to avoid cerebral edema resulting from SIADH (15). More recent data, however, have led to the hypothesis that an elevated anti-diuretic hormone and the concomitant increase in extracellular water may be part of a compensatory mechanism to overcome elevated ICP and maintain

adequate cerebral blood flow (16,17). Routine restriction of fluids should no longer be considered standard (1). If the patient is not dehydrated, the cardiovascular system is stable, and the serum sodium is above 135 mEq/L, maintenance fluids can be initiated using a solution containing one-fourth to one-half normal saline in 5% dextrose.

Increased ICP

The upper limit of normal ICP is about 50 mm H_2O in neonates and 85 mm H_2O in older infants and children, but it can be much higher in CNS infections. In patients with suspected intracranial hypertension, the head of the bed is elevated 15 to 30 degrees. Although the practice is somewhat controversial, some physicians use mannitol (0.25 to 1.0 g/kg infused over 10 minutes), with or without diuretics, to treat intracranial hypertension. Hyperventilation is another effective means to temporarily decrease ICP in the severely affected patient. If hyperventilation is utilized, the $PaCO_2$ should be maintained at 25 to 30 mm Hg. ICP should be monitored continuously in patients requiring hyperventilation and mannitol infusions.

Several authors have advocated the use of adjunctive dexamethasone therapy for bacterial meningitis, particularly in cases of HIB (18,19). However, subsequent research has failed to demonstrate any improvement in neurologic or developmental outcome in children who received steroids for bacterial meningitis (20). Other authors, however, have pointed out that, in light of the low incidence of side effects and the potential benefits, administration of steroids remains appropriate (21), particularly if CSF Gram stain or epidemiologic clues point to a likely case of HIB meningitis. The American Academy of Pediatrics Committee on Infectious Diseases has suggested the use of dexamethasone in suspected bacterial meningitis but has stopped short of recommending it as routine therapy unless disease is caused by HIB (22). If dexamethasone is used, it should be given only to children older than 6 weeks of age with suspected bacterial meningitis, at a

dose of 0.15 mg/kg intravenously just before the first parenteral dose of antibiotic.

Seizures

Early seizure activity occurs in 20% to 30% of patients with bacterial meningitis. Effective anticonvulsants include diazepam or lorazepam acutely and phenobarbital or phenytoin as maintenance. Seizures associated with hyponatremia require infusion of hypertonic sodium solutions. Generally, 4 mL/kg of 3% NaCl is infused over 10 minutes; repeat doses may be necessary if the seizure continues.

Disseminated Intravascular Coagulation

Treating the underlying disease process and correcting the shock and metabolic derangements constitute the best approach to reversing disseminated intravascular coagulation (DIC). If the patient is actively bleeding from peripheral sites or from the gastrointestinal or urinary tract, treatment options include: (1) platelet transfusions to increase the count to above 50,000/μL, (2) vitamin K to correct a prolonged prothrombin time, and (3) infusions of fresh-frozen plasma to correct a prolonged activated partial thromboplastin time. Heparin therapy may be considered in cases of DIC with thrombotic manifestations, although its use in this setting is controversial.

Antimicrobial Therapy

Table 278.3 lists the antibiotics and dosages suggested for the initial therapy of suspected bacterial meningitis. Because penicillin- and cephalosporin-resistant pneumococci have been reported throughout the United States, vancomycin should be added to the regimen any time infection caused by *S. pneumoniae* is suspected. Previous concerns about reduced penetration of vancomycin into the CNS after administration of dexamethasone appear to be unwarranted (23).

TABLE 278.3
Initial Antimicrobial Therapy for Suspected Bacterial Meningitis

Age	Drug	Dosage (mg/kg)
Newborn: to 30 days	Ampicillin	50–75
	and	
	Gentamicin	2.5
	or	
	Cefotaxime	50
30 days to 3 months	Ampicillin	
	and	
	third-generation cephalosporin	50–75
	• Ceftriaxone	50
	• Cefotaxime	75
>3 months	Ceftriaxone or cefotaxime	
	and	
	Vancomycin	15

Sometimes, the results of the initial CSF examination do not distinguish between a bacterial and a viral process. If patients have been pretreated with antibiotics, are younger than 6 months, or are clinically unstable, they should be initially managed as if bacterial meningitis were present.

If HSV encephalitis is suspected, acyclovir therapy is instituted at 20 mg/kg every 8 hours.

CRITICAL INTERVENTIONS

- Consider bacterial meningitis and perform an LP in lethargic or irritable infants, even in the absence of classic signs of meningitis.
- Consider repeat LP if the evolving clinical setting suggests meningitis, even if a CSF culture obtained hours or days earlier was negative.
- Obtain a blood culture before instituting antibiotic therapy for suspected bacterial meningitis.
- Initiate antibiotics prior to CT scanning and the availability of CSF results in any patient with suspected meningitis.

DISPOSITION

Pediatric infectious disease consultation may be warranted for the management of CNS infections in children. Neurosurgical consultation for placement of an ICP-monitoring device may also be required.

Patients with bacterial meningitis or HSV encephalitis require immediate hospitalization with intensive monitoring. CNS infections of probable enteroviral or arboviral origin may require hospitalization for diagnostic purposes or for supportive care.

If clinical signs and symptoms and laboratory analysis of CSF suggest viral meningitis, outpatient management may be appropriate (24). Some authors suggest observation for 4 to 8 hours, followed by a second LP to help confirm the diagnosis (10). If the second CSF analysis reveals lymphocyte predominance, no significant worsening of pleocytosis, normal glucose and protein, and continued absence of bacteria on Gram stain, bacterial meningitis is highly unlikely. A recently validated bacterial meningitis score has been shown to have a high negative predictive value for bacterial meningitis and can also be used to identify candidates for outpatient therapy (Table 278.4) (24).

TABLE 278.4
Risk Factors for Bacterial Meningitis: The Bacterial Meningitis Score[a]

Bacteria detected on CSF gram stain
CSF absolute neutrophil count ≥1,000 cells/μL
CSF protein ≥80 mg/dL
Peripheral blood absolute neutrophil count ≥10,000 cells/μL
History of seizures before or at the time of presentation

[a]No risk factors = very low risk, negative predictive value for bacterial meningitis 99.9%.

Source: From Nigrovic LE, Kuppermann N, Macias CG. Clinical prediction rule for identifying children with cerebrospinal fluid pleocytosis at very low risk of bacterial meningitis. *JAMA*. 2007;297:52–60.

Transport to a pediatric referral center should be strongly considered for any child with bacterial meningitis. If the LP has been performed, an aliquot of the CSF should be sent with the patient,

along with documentation of clinical management up to the point of transfer.

CONTACT PROPHYLAXIS

If meningitis is caused by *N. meningitidis* or HIB, rifampin chemoprophylaxis should be considered for the child's household contacts. The dosage regimen is 10 mg/kg (maximum dose, 600 mg) every 12 hours for four doses and 20 mg/kg (maximum dose, 600 mg) once daily for 4 days, respectively. Chemoprophylaxis is given to household contacts of children with HIB meningitis only if there is at least one unvaccinated household member younger than 48 months. Rifampin should not be given to a pregnant patient. Medical personnel exposed to a patient with meningococcal infection need chemoprophylaxis only if that exposure was intimate (e.g., mouth-to-mouth resuscitation). The use of appropriate isolation precautions (mask and gown, hand washing) for suspected cases of meningococcal disease eliminates any need for prophylaxis in most situations.

Common Pitfalls

- Failure to consider meningitis in infants with fever without a source.
- Failure to consider CNS infection in children with vomiting.
- Excluding the diagnosis of bacterial meningitis despite strong clinical clues, even when the CSF white cell count is normal or the Gram-stain is negative for bacteria
- Failure to order a Gram-stained smear of the CSF when bacterial meningitis is suspected.
- Failure to consider a CNS infection in a child who has had a simple febrile seizure. Although LP is not mandatory, it should be considered in a child younger than 18 months of age, especially if the child has not returned to baseline mental status.
- Failure to document the physical examination thoroughly, particularly the child's general appearance.
- Failure to provide adequate discharge instructions, especially reasons for immediate return to the emergency department.

CHAPTER 279 Human Immunodeficiency Virus

Joseph A. Church and Jeffrey F. Linzer, Sr.

In the early 1980s, children were identified with clinical features similar to severe combined immunodeficiency (SCID) but with distinct epidemiologic and pathologic findings. These first cases of pediatric acquired immunodeficiency syndrome (PAIDS) were reported in 1982. By 1983, the causative agent of AIDS was identified as human immunodeficiency virus (HIV) (1).

HIV is an RNA retrovirus that selectively infects T-cells and cells of the monocyte lineage. The host cell targets of HIV are critical components of the immune system (2). When confronted with pathogens, these cells normally produce a coordinated, protective effector response. The molecular signals that activate normal cell responses to pathogens are read by the HIV proviral DNA as signals to initiate replication.

Three pathologic consequences of HIV infection induce recognizable patterns of clinical disease: progressive immunologic attrition and immune deficiency, central nervous infection, and uncontrollable immune activation (3). Because functional CD4+ T-cells are required for the generation of protective, antigen-specific T-cell and antibody responses, T-cell loss and impaired T-cell production eventually induce an acquired severe immune deficiency and progressive susceptibility to opportunistic infections (OIs). Neurons in the central nervous system (CNS) are not specific targets for HIV, although it infects and activates local microglial cells. These activated macrophage-like cells generate a variety of cytokines that

cause activation-induced programmed cell death of adjacent neurons, resulting in signs and symptoms of neuroencephalopathy. HIV may also induce an inappropriate and uncontrolled activation of infected target cells, producing a variety of proliferative disorders such as lymphoid interstitial pneumonitis (LIP), lymphadenopathy, hepatosplenomegaly, and systemic features of chronic infection, including fatigue, fever, and wasting.

In 2008 the Centers for Disease Control and Prevention (CDC) redefined the criteria for HIV infection and *acquired immunodeficiency syndrome* (AIDS) in children less than 13 years of age (4). Although in the revised definitions, children less than 18 months old whose mother is HIV positive and have an AIDS defining condition (see Table 279.1) are considered to have been infected, confirmatory testing is still strongly encouraged. Children 18 months of age and older must have laboratory confirmed evidence of infection even if they have an AIDS defining condition, in order to be considered infected with the virus. The CDC also has developed a specific classification system to describe the immunologic and clinical features of the disease in children (Table 279.2). These categories are combined to provide a pediatric HIV classification which defines patients at their worst clinical and immunologic states; the assigned class is not be upgraded even if a patient improves with treatment (Table 279.3) (5).

TABLE 279.1
AIDS-Defining Conditions in Children <13 Years

Bacterial infections, multiple or recurrent	LIP or PLH complex
Candidiasis of esophagus, bronchi, trachea, or lungs	Lymphoma, Burkitt (or equivalent term), immunoblastic (or equivalent term, or primary, of brain
Coccidioidomycosis, disseminated or extrapulmonary	*M. avium* complex or *Mycobacterium kansasii*, disseminated or extrapulmonary
Cryptococcosis, extrapulmonary	*Mycobacterium tuberculosis* of any site, pulmonary, disseminated, or extrapulmonary
Cryptosporidiosis, chronic intestinal (>1 month's duration)	*Mycobacterium*, other species or unidentified species, disseminated or extrapulmonary
Cytomegalovirus disease (other than liver, spleen, or nodes), onset at age >1 month	*Pneumocysti jirovecii* pneumonia
Encephalopathy, HIV related	Progressive multifocal leukoencephalopathy
Histoplasmosis, disseminated or extrapulmonary	*Salmonella* septicemia, recurrent
Isosporiasis, chronic intestinal (>1 month's duration)	Toxoplasmosis of brain, onset at age >1 month
Kaposi sarcoma	Wasting syndrome attributed to HIV
Herpes simplex: chronic ulcers (>1 month's duration) or bronchitis, pneumonitis, or esophagitis (onset at age >1 month)

TABLE 279.3
CDC Classification System for HIV-Infected Children <13 Years of Age

Immunologic Category	Clinical Categories[a]			
	N: No Signs/ Symptoms	A: Mild Signs/ Symptoms	B: Moderate Signs/Symptoms	C: Severe Signs/ Symptoms
No evidence of suppression	N1	A1	B1	C1
Evidence of moderate suppression	N2	A2	B2	C2
Severe suppression	N3	A3	B3	C3

[a]For definitions of mild, moderate and severe symptoms, see Centers for Disease Control and Prevention. 1994 Revised classification system for human immunodeficiency virus infection in children less than 13 years of age. *MMWR Morb Mortal Wkly Rep.* 1994;43(RR-12):1–10.

With recommendations for universal HIV screening of all pregnant women and effective pre- and post-natal therapy of "at risk" babies, maternal to child transmission is less than 2%. However, adolescents and young adults (13 to 29 years old) accounted for 39% of all new HIV infections in 2009. The HIV infection rate in children under 13 years has remained relatively stable between 2008 and 2011 at ~0.4% (6). The majority of infections are still acquired perinatally. Fortunately, the estimated rate of PAIDS is >0.01%

CLINICAL PRESENTATION

The initial presentation and assessment of an HIV-infected child may differ depending upon whether or not the diagnosis of HIV infection has been made previously (3,7). The child with perinatally acquired HIV may appear to be growing normally and to have no more than the usual number of routine childhood infections. Therefore, previously undiagnosed HIV-infected children may present through the emergency department (ED) with their first clinical manifestations of HIV-associated disease, and a degree of suspicion must be kept for HIV even in relatively healthy older children.

Additionally, as teens engage in high-risk behavior, they too may present to the ED with complications of previously undiagnosed HIV infection.

HIV infection should be considered in children who present with unexplained poor growth or developmental delay or with recurrent or chronic infections. Recurrent infections do not need to be severe or debilitating, and the most common infections seen early in the course of HIV-associated immunodeficiency are frequent otitis media, sinusitis, bacterial pneumonia, adenitis, and diarrhea. Any OI

immediately suggests an underlying immune deficiency. The most common presenting physical findings in previously undiagnosed HIV-infected children are lymphadenopathy, especially involving cervical and axillary lymph nodes, and hepatic or splenic enlargement. Parotid gland enlargement may also be seen. The presence of recurrent or chronic oral candidiasis especially in a child older than 1 year suggests immune deficiency. Common hematologic findings in HIV-infected children include anemia, neutropenia, and, in approximately 5% of undiagnosed HIV-infected children, "idiopathic" thrombocytopenia. Blood chemistry abnormalities may include nonspecific liver enzyme elevations, hypoalbuminemia, and hyperproteinemia with an increased globulin fraction. The erythrocyte sedimentation rate is often markedly elevated.

Acute manifestations of an OI may be the initial presenting process in a child with undiagnosed HIV. *Pneumocystis jiroveci* pneumonia (PJP) remains the most common presenting OI in undiagnosed children. Although typically presenting at <2 years of age, PJP may occur in a child at any time and depends upon the status of an individual patient's T-cells. Symptoms of PJP include dyspnea, tachypnea, cough, and fever that may be slowly progressive over several weeks. Physical examination often reveals clear lung sounds and disproportionate hypoxemia. The severity of symptoms may range from a mild repetitive cough to severe respiratory distress. Chest radiography shows a diffuse interstitial pattern often disproportionately mild compared to the patient's hypoxemia and respiratory distress. Lymphoid interstitial pneumonitis (LIP) and pulmonary lymphoid hyperplasia (PLH) also cause respiratory symptoms and may mimic infection or reactive airway disease. In contrast to PJP, LIP and PLH often have radiographic findings worse than respiratory symptoms would suggest. Children with this process often have generalized lymphadenopathy and hepatosplenomegaly and may display digital clubbing. The most common organisms causing respiratory infections in HIV-infected children remain the typical pediatric respiratory pathogens such as *Streptococcus pneumonia, Haemophilus influenzae,* and *Moraxella catarrhalis.*

Children with profound immune deficiency may present to the ED with a variety of other OIs. *Mycobacterium avium* complex presents with prolonged fevers, night sweats, chronic diarrhea, abdominal pain, and weight loss. Chronic oral thrush is common, and esophageal candidiasis should be suspected in a child with oral thrush accompanied by dysphagia, irritability, and weight loss. Diarrhea is common. Although at times related to persistent gastrointestinal infections with "routine" organisms such as Salmonella, Shigella, and Campylobacter, HIV-infected children are particularly at high risk for *Clostridum difficile, Giardia,* cryptosporidium, and cytomegalovirus (CMV) enteritis. Disseminated toxoplasmosis, histoplasmosis, and cryptococcosis, although uncommon, may be seen in children. Herpes virus infections—herpes simplex virus (HSV), varicella-zoster virus (VZV) and CMV—are often particularly severe and may present as disseminated disease. CMV retinitis, a common cause of vision loss in adult HIV patients, is uncommon in children but can occur with advanced disease and may present to the ED as acute blurry vision. Malignancies, especially B-cell lymphomas, occur at an increased rate with HIV infection and may occur in the CNS or gastrointestinal tract. Kaposi sarcoma, however, is rare in children. Acute cardiac and renal manifestations are uncommon, but cardiomyopathy with congestive heart failure and acute renal failure has been described. Chronic HIV-associated encephalopathy and developmental delay are common in untreated children, and acute CNS manifestations such as infection, space-occupying lesions, and thromboembolic events may occur. Infected children are at risk for sepsis and meningitis with the usual pediatric pathogens, and patients may be particularly susceptible because of compromised ability to respond to routine immunizations.

Less-acute but common presentations to the ED include infectious skin eruptions, such as molluscum, verrucae, and drug eruptions. The child with HIV-associated immune compromise is at greater risk for severe HSV and VZV infections and may present with recurrent or persistent chicken pox, varicella zoster, or mucocutaneous herpes simplex infections. Oral aphthous ulcers are common and present as

painful, shallow oropharyngeal ulcers that often result in decreased oral intake, weight loss, and, at times, dehydration. Aphthous ulcers need to be differentiated from oral HSV lesions, as corticosteroids are useful in the treatment of the former and contraindicated in the latter.

Children known to be infected with HIV often present to the ED with a different constellation of chief complaints (7). Patients who are adherent to their highly active antiretroviral therapy (HAART) are very unlikely to develop an OI, and acute infections most often reflect routine childhood illnesses. More commonly, ED visits are associated with adverse effects of patients' treatment regimens. Acute pancreatitis can be seen with several antiretroviral (ARV) agents and can be severe and life threatening. Drug eruptions ranging from mild nonspecific erythroderma and urticaria to overwhelming Stevens–Johnson syndrome may be seen with agents used for PJP prophylaxis (trimethoprim–sulfamethoxazole [TMP–SMX]) or ARV agents (e.g., abacavir and nevirapine). Nausea, vomiting, and liver function abnormalities are commonly seen in patients on HAART. Drug-induced hematologic abnormalities that may present to the ED include thrombocytopenia-associated bleeding, anemia-associated congestive heart failure, and granulocytopenia-associated secondary infections, such as those caused by *S. aureus* and *Pseudomonas aeruginosa.*

DIFFERENTIAL DIAGNOSIS

Any of the SCID syndromes may present identically to HIV. Children with either autosomal recessive or X-linked SCIDs often present with overwhelming infections within the first 6 months of life, although later presentation may occur. Patients with DiGeorge syndrome may develop OIs, but these patients usually have associated conotruncal congenital heart disease, hypocalcemia, or typical facial dysmorphisms. Primary antibody deficiencies including X-linked agammaglobulinemia and common variable immune deficiency typically present with recurrent upper and lower respiratory tract infections caused by encapsulated bacteria. *Giardia* and enteroviral disease are also commonly seen in these patients.

Lymphoma, leukemia, and other malignancies can present with weight loss, organomegaly, lymphadenopathy, cytopenias, and OIs. Cystic fibrosis is also associated with recurrent pneumonias, sinus disease, chronic diarrhea, and poor weight gain. Autoimmune diseases such as systemic lupus erythematosus and systemic juvenile rheumatoid arthritis and metabolic and mitochondrial diseases may present with multiple features suggestive of immune deficiency. Many chronic conditions may be associated with secondary immunodeficiency including protein calorie malnutrition, zinc deficiency, nephrotic syndrome, inflammatory bowel disease, and protein-losing enteropathies.

In infants younger than 3 months, TORCH infections (toxoplasmosis, rubella, CMV, HSV, syphilis) may present with features similar to HIV.

ED EVALUATION

Assessment in the ED will depend upon whether the patient is known to be infected with HIV or is presenting with a suspected but undiagnosed immune deficiency (7). A careful physical examination and history should assess factors listed in Table 279.4. However, absence of known risk factors should not override clinical suspicion for HIV. A child with findings strongly suggestive of immune deficiency should be considered for hospitalization for comprehensive evaluation. There are several highly sensitive and specific rapid HIV tests approved for use in the United States. Fourth-generation immunoassays detect IgM and IgG antibodies and p24 antigen and are highly sensitive at detecting early infection. Unfortunately, results are not immediately available with these newer assays. Although not as sensitive for early detection, several second-generation devices that detect antibody only are designed for point-of-care testing and provide results within 20 minutes.

TABLE 279.4
Indications for HIV Testing in Children Presenting to the ED

History of parental HIV infection
Signs of congenital viral infection
Suspected OI
History of recurrent, severe, bacterial infections
Hepatosplenomegaly, lymphadenopathy
Unexplained wasting, myopathy, hepatitis, carditis, nephritis, developmental regression, neuropathy, encephalopathy

For the child with known HIV infection, ED evaluation should address the presenting problems in the context of the patient's immunologic status. The risk of OI is related to the degree of immune deficiency and adherence to a HAART regimen. In general, children who are in CDC category 1 (no evidence of immune suppression) may receive the same evaluation as a noninfected child with similar clinical symptoms. Children in more advanced categories are at higher risk of serious illness, and more intensive evaluations are indicated.

Although potentially a sign of underlying malignancy, fever is usually an indication of secondary infection. In most children, a routine complete blood count, appropriate cultures, and indicated radiographs should be performed. In children with severe immune compromise, blood cultures should also be obtained for acid-fast bacilli, CMV, and adenovirus. Pulse oximetry or blood gases are indicated for patients with cough, wheeze, or respiratory distress. Nasal pharyngeal washings for rapid viral diagnostic assessment should be sent, and sputum should be obtained in older children. For acute diarrheal disease, stool examinations are indicated for routine bacterial and rotavirus infections, ova, and parasites *Giardia* and *C. difficile*. In children with advanced HIV disease, evaluation for cryptosporidium, acid-fast bacilli, CMV, and adenovirus would be added to this list. Where dehydration is a consideration, serum electrolytes, calcium, and magnesium levels should be monitored. For children presenting with acute abdominal pain, serum amylase and lipase and tests of liver function should be ordered. Abdominal imaging may be indicated for patients with severe or persistent pain. For acute rashes suggestive of drug hypersensitivity, a history of recent medication changes should be sought. Skin lesions appearing infectious in origin should be cultured. Children with acute CNS

symptoms should have appropriate imaging and lumbar puncture if deemed safe and appropriate.

HIV infection is often associated with generalized lymphadenopathy. Differentiation from chronic parotid gland involvement is sometimes difficult. Acute infectious lymphadenitis or focal bacterial parotitis may complicate long-term lymphadenopathy or parotid gland swelling. HIV-associated B-cell lymphoma may present as a rapidly growing local adenopathy in a patient irrespective of T-cell level.

Adverse medication reactions are very common in HIV patients and may develop acutely or after prolonged exposure to ARV drugs. The primary side effects associated with ARV agents are listed in Table 279.5 (8). The long-term adverse impact of ARV agents on metabolism and bone is being seen more frequently. Many agents may cause acute, severe lactic acidosis. HIV-associated lipodystrophy known to affect adults is now being seen more commonly in children and is associated with increased abdominal girth, dorsocervical fat accumulation, and peripheral fat loss characterized by thinning of the face, extremities, and buttocks. Metabolic complications include insulin resistance leading to frank diabetes, hyperlipidemia with elevated cholesterol, and triglyceride levels, leading potentially to early coronary artery disease, and osteopenia with increased risk for spinal compression and extremity fractures. ARV agents, particularly the protease inhibitors, have pharmacologic interactions with many other agents (e.g., prolongation of activity of midazolam). Many other drug interactions have been documented, and clinicians must exercise caution when adding new drugs to an HIV-infected patient's treatment regimen.

Current guidelines from the Health and Human Services panel on ARV therapy and medical management of HIV-infected children recommend discontinuing all components of a child's drug regimen in severe or life-threatening toxicity. The toxic effect and the suspected ARV should clearly be documented in the medical record. Unless the recent results of therapeutic drug monitoring showing concentration above the normal therapeutic range are available to

the ED physician, dose reduction is not considered an option in the setting of ARV toxicity (8).

KEY TESTING

- Known HIV infection
  - Fever: Degree of immune suppression
    - None: Evaluate as if noninfected
    - Moderate: Complete blood count, appropriate cultures, rapid respiratory viral testing
    - Severe: As above plus test for acid-fast bacillus, cytomegalovirus, and adenovirus
  - Respiratory symptoms: Chest X-ray, rapid respiratory viral testing, and sputum culture
  - Acute gastrointestinal illness: Serum electrolytes, calcium, and magnesium levels, stool culture, rotavirus antigen test, adenovirus rapid test
    - Ova and parasites test, *Giardia* and *C. difficile* toxin should be considered for primary diarrheal illness
  - Acute abdominal pain: Serum amylase and lipase and liver function testing
- HIV exposure evaluation: Rapid HIV1/2 test, hepatitis B surface antibody and antigen, hepatitis C test

ED MANAGEMENT

Three principles guide ED management of children with HIV: HIV is not spread by routine clinical contact with patients or their families; the risk of any acute process being a serious one is inversely related to the patient's T-cell count; and close communication with the patient's HIV specialist is crucial.

Presenting illness in an HIV-infected child with intact T-cells can generally be managed in a manner similar to that of the same process in a noninfected child. For other HIV-infected children, the degree of immune suppression (CD4+ T-lymphocyte count or percentage) (Table 279.2) needs to be considered when ED management is initiated. Importantly, ED-identified physical or

laboratory abnormalities may be known to the primary HIV health-care provider as chronic conditions, and the primary service may be aware of psychosocial factors unique to the patient and family that need to be incorporated into ED management.

TABLE 279.5
Primary Side Effects Associated with ARV Agents

ARV Class/Agent	Primary Side Effects and Toxicities
Nucleoside Reverse Transcriptase Inhibitors	
Zidovudine (Retrovir; ZDV; AZT)	Anemia, neutropenia, nausea, headache, insomnia, muscle pain, and weakness
Lamivudine (Epivir; 3TC)	Abdominal pain, nausea, diarrhea, rash, and pancreatitis
Emtricitabine (Emtriva; FTC)	
Stavudine (Zerit; d4T)	Peripheral neuropathy, headache, diarrhea, nausea, insomnia, anorexia, pancreatitis, increased liver function tests (LFTs), anemia, and neutropenia
Didanosine (Videx; ddI)	Pancreatitis, lactic acidosis, neuropathy, diarrhea, abdominal pain, and nausea
Abacavir (Ziagen; ABC)	Nausea, diarrhea, anorexia, abdominal pain, fatigue, headache, insomnia, and hypersensitivity reactions
Tenofovir (Viread; TNV; TDF)	Nausea, diarrhea, vomiting
Nonnucleoside Reverse Transcriptase Inhibitors	
Nevirapine (Viramune; NVP)	Rash (including case of Stevens-Johnson syndrome), fever, nausea, headache, hepatitis, and increased LFTs
Delavirdine (Rescriptor; DLV)	Rash (including case of Stevens-Johnson syndrome), nausea, diarrhea, headache, fatigue, and increased LFTs
Efavirenz (Sustiva; EFV)	Rash (including cases of Stevens-Johnson syndrome), insomnia, somnolence, dizziness, trouble concentrating, and abnormal dreaming.
Protease Inhibitors	
Indinavir (Crixivan; IDV)	Nausea, abdominal pain, nephrolithiasis, and indirect hyperbilirubinemia
Nelfinavir (Viracept; NFV)	Diarrhea, nausea, abdominal pain, weakness, and rash
Ritonavir (Norvir; RTV)	Weakness, diarrhea, nausea, circumoral paresthesia, taste alteration, and increased cholesterol and triglycerides
Saquinavir (Invirase [formerly Fortovase]; SQV)	Diarrhea, abdominal pain, nausea, hyperglycemia, and increased LFTs
Amprenavir (Agenerase; APV) Fos-Amprenavir (Lexiva; *f*-APV)	Nausea, diarrhea, rash, circumoral paresthesia, taste alteration, and depression
Lopinavir/Ritonavir (Kaletra; LPV/RPT)	Diarrhea, fatigue, headache, nausea, and increased cholesterol and triglycerides
Atazanavir (Rayataz; ATV)	Jaundice, hyperbilirubinemia, nausea, vomiting, headache, diarrhea, rash
Tipranavir (Aptivus; TPV)	CNS hemorrhage, hepatitis, rash, increased cholesterol and triglycerides
Darunavir (Prezista; DRV)	Nausea, diarrhea, abdominal pain, headache, lipodystrophy, increased cholesterol and triglycerides
Entry Inhibitors	
Enfuvirtide (Fuzeon; T-20)	Injection site reactions; household exposure to contaminated needles/syringes
Maraviroc (Selzentry; MVC)	Cough, rash, muscle and joint pain, abdominal pain, dizziness
Integrase Inhibitor	
Raltegravir (Isentress; RAL)	Diarrhea, nausea, headache, increased creatine kinase

The insight of the patient's HIV provider will help guide the empiric antibiotic treatment of a child presenting to the ED with fever. The specific antibiotic regimen is based on the source of infection, likely organisms, and degree of T-cell compromise. Children with normal T-cells may be treated with oral antibiotics alone. Parenteral ceftriaxone (50 to 75 mg/kg) followed by a course of oral antibiotics effective against beta-lactamase positive agents is a good choice for community-acquired pneumonia, acute otitis media, or sinusitis in a patient with mild-to-moderate immunologic

suppression but stable T-cell numbers. Children with advanced HIV disease require more aggressive antibiotic intervention. Initial treatment should be with high-dose parenteral ceftriaxone (75 to 100 mg/kg); additional antibiotics including vancomycin or piperacillin and tazobactam may also be considered. Fever with granulocytopenia, which may develop at any time as a complication of ARV therapy, requires broad-spectrum antibiotic coverage, as does the patient with fever and an indwelling central venous catheter. The ED physician should have a low threshold for admission to a facility with specialists in PAIDS, especially for the child with severe immune suppression.

Antiviral chemotherapy often is needed in children with HIV. Empiric influenza treatment should be started on any HIV-infected children with a febrile viral illness during influenza season regardless of the result of a rapid flu test. Acyclovir may be used for outpatient management for varicella prophylaxis following exposure.

Although HIV-positive infants younger than 1 year may develop PJP at any T-cell level, older patients with severe T-cell suppression are at particular risk for this complication, particularly if adherence to prescribed prophylaxis is inconsistent. Patients with PJP usually present with a history of progressive cough, tachypnea, shortness of breath, dyspnea, and intermittent fever, which may be low grade. Auscultation of the chest often reveals an expiratory grunt without other adventitious sounds. Hypoxemia is demonstrable with pulse oximetry and may be exacerbated with simple exercise. Chest radiograph may show only minimal changes; marked interstitial infiltration reflects very advanced disease and a guarded prognosis. Any patient suspected of having PJP should be hospitalized at a center familiar with the management of this disorder. Bronchoalveolar lavage is particularly useful in confirming the diagnosis. TMP-SMX is the antibiotic of choice, and systemic corticosteroids are indicated as adjunctive therapy in these patients. HIV-infected children, even those with T-cells sufficient to avoid OIs, are at increased risk for pneumonias and other respiratory tract infections with “routine” organisms including *S. pneumoniae, M. catarrhalis,* and *H. influenzae.* They are also at risk for reactive airway

disease, and more than 30% of patients require bronchodilators or more intense therapy for asthma. Differentiating between an acute asthma attack and a serious acute infectious process is essential.

The most common cause of diarrhea in HIV-infected children is their ARV therapy. Dietary changes and loperamide are usually sufficient to control symptoms. Dehydration is treated with oral or intravenous rehydration depending on severity. Because of the increased risk for infectious enteritis, HIV-positive children presenting to the ED with diarrhea should be screened for salmonella, shigella, Campylobacter, and parasitic infections with *Giardia lamblia* and cryptosporidium. *C. difficile* and intestinal candidiasis may be complications of long-term prophylactic antibiotics. Nonspecific enteritis commonly seen in children with long-term HIV disease may be associated with electrolyte imbalance, malabsorption, and wasting.

It is not appropriate to institute or make changes in an individual's ARV therapy, prophylactic therapy, or other chronic medical treatment in the ED. Any such changes should be made only after discussion with patient's HIV health-care provider.

CHEMOPROPHYLAXIS AFTER EXPOSURE TO HIV

Children may present to the ED after exposures that put them at risk for HIV infection. Examples include accidental puncture wounds during play with discarded needles or from needles in the home and sexual abuse. Nonoccupational post-exposure prophylaxis (nPEP) is recommended for children after substantial exposure risk to blood, genital secretions, or other potentially infected body fluids of a person known to be HIV infected. Nonoccupational PEP should also be considered in the situation where the HIV status is unknown, such as following a sexual assault (Fig. 279.1). The most effective outcomes occur when nPEP is started within 72 hours of exposure when transmission of the virus is more likely to be interrupted (9). However, nPEP may be started more than 72 hours post-exposure if, in the clinicians' judgment, there is a serious risk of transmission and the benefits of therapy outweigh the risks.

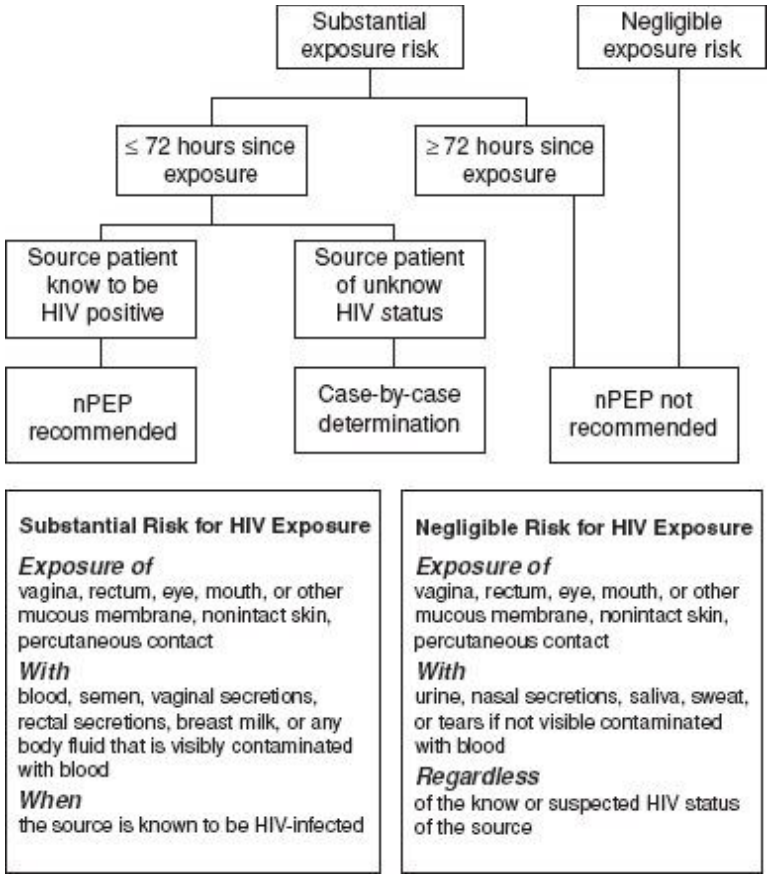

FIGURE 279.1 Algorithm for evaluation and treatment of possible nonoccupational HIV exposures. (From Centers for Disease Control and Prevention. Antiretroviral postexposure prophylaxis after sexual, injection-drug use, or other nonoccupational exposure to HIV in the United States: Recommendations from the U.S. Department of Health and Human Services. *MMWR Recomm Rep.* 2005;54[RR-2]:8.)

Generally a three-drug HAART regime is used to provide maximal suppression of virus replication. There is no clear evidence which regimen provides the best outcome. Current recommendations include use of either a nonnucleoside, protease inhibitor or integrase inhibitor combined with two nucleoside reverse transcriptase inhibitors (Table 279.6) (9–11). The course of therapy is for 28 days. Compliance may be improved if the child is sent home with a 3- to 5-day supply of medications. The child should be tested for HIV antibodies at the initiation of post-exposure prophylaxis to confirm the absence of pre-existing HIV infection. Post-exposure prophylaxis

should be offered in conjunction with appropriate counseling as to the risks and benefits of ARV therapy and the infectious risk of the exposure and after arrangements are made for ongoing counseling and follow-up testing.

TABLE 279.6
Postexposure Prophylaxis Regime for Children

Regime Type	Nucleoside Reverse Transcriptase Inhibitors (One Drug from Each Column)	
Nonnucleoside: Efavirenz (EFV)	Lamivudine (3TC) or Emtricitabine (FTC)[a]	Zidovudine (ZDV) or Tenofovir (TDF)[a]
Protease inhibitor: Lopinavir/Ritonavir (LPV/r) (Kaletra®)	Lamivudine (3TC) or Emtricitabine (FTC)	Zidovudine (ZDV)
Integrase inhibitor: Raltegravir (RAL)	Emtricitabine (FTC)[a]	Tenofovir (TDF)[a]

[a]FTC and TDF are available in a combination formulation (Truvada®), approved for children ≥12 years and ≥35 kg.

CRITICAL INTERVENTIONS

- Patients suspected of having immune deficiency should not be given live virus vaccine; all blood products required by such patients should be irradiated and CMV negative.
- Fever in an HIV-infected patient suggests infection. Appropriate investigations (such as complete blood count, blood culture, chest radiograph, urinalysis, lumbar puncture) are indicated.
- Consider HAART side effects as the cause of symptoms such as rash, abdominal pain, and other gastrointestinal symptoms.
- In an HIV-infected patient, the risk for a more serious disease is inversely related to the patient's T-cell count. Immunosuppressed children should receive more intensive evaluation and treatment interventions than immunologically normal children.
- A child at risk for HIV by either history or suggestive clinical findings should be offered rapid HIV testing and managed

accordingly.

DISPOSITION

As with any chronic disorder, children with HIV are best followed up by a primary service experienced in the multidisciplinary management of the disease. Children who are suspected of having undiagnosed HIV and who do not have compelling clinical findings should be referred to a pediatric infectious disease or other HIV specialist for urgent consultation. Discussion with the consultant prior to discharge from the ED can help assess whether the child can be safely discharged and to arrange follow-up. Known HIV-infected children who are manageable at home may be discharged from the ED after consultation with the primary HIV health-care service and arrangement for follow-up.

Children requiring hospitalization should be carefully evaluated to determine whether admission to an intensive care or regular inpatient unit is required. If the hospital is not equipped to manage seriously ill HIV-infected children or if the necessary specialists are not available, the patient should be transported to an appropriate center by qualified transport personnel.

Common Pitfalls

- Failure to appreciate the clinical latency from infection to manifestation of HIV disease may be years. Perinatally infected children may present with their first complications at 10 years or older.
- Failure to question histories. Not all parents will volunteer that their child is HIV infected, and others may deny their own risk factors. Decisions to test or treat a child as HIV infected may need to be based on clinical suspicion alone.
- Failure to recognize OIs in patients with known or suspected immune deficiency. In any suspected immune-deficient patient younger than 1 year, the presence of tachypnea and hypoxia suggest PJP, and empiric therapy should not be withheld while waiting for a definitive diagnosis. Children prescribed appropriate

PJP prophylaxis may develop the disease if they are nonadherent to their prophylaxis regimen.

- Failure to appreciate the significance of oral thrush. Any child older than a year with persistent or recurrent oral thrush should be considered to be immune deficient.

CHAPTER 280

Sickle Cell Disease in Children

Nadeem U. Qureshi, James M. Gerard, and Jabeen Fayyadh

Sickle cell disease (SCD) represents a spectrum of inherited hemoglobin defects that are characterized by dysmorphic red blood cells, impaired homeostatic balance involving the vascular endothelium and nitric oxide, and subsequent microvascular occlusion. It is one of the most common severe monogenic disorders (1). The molecular basis of the disease is the substitution of 17th nucleotide from thymine to adenine forming valine instead of glutamic acid in the sixth position of the globin beta chain (1). This change causes the crystallization of the hemoglobin molecules in conditions of relative hypoxia, low pH, cold, dehydration of the RBCs, and infections (1).

These patients may present with signs and symptoms involving any organ. The majority of emergency department (ED) visits are because of recurrent vaso-occlusive crisis, invasive infections, acute chest syndrome (ACS), stroke, and priapism (5). The severity of clinical manifestations of these syndromes depends on the presence of specific type of hemoglobinopathy (Table 280.1). As life expectancy has been increasing for patients with SCD, the number of ED visits per year has risen (3).

TABLE 280.1
Sickle Cell Syndromes (Specific Hemoglobinopathy and Associated Findings)

Hemoglobinopathy	Clinical Presentation	Hb (g per dL)	Hb S (%)	Hb A (%)	Hb A_2 (%)	Hb F (%)
SCT (carrier)	Asymptomatic	Normal	40	60	<3.5	0
SCD (different variants)						
Hb SS (sickle cell anemia)	Severe	6–8	>90	0	<3.5	<10
Hb S beta°—thalassemia	Moderate/severe	7–9	>80	0	>3.5	<20
Hb S beta—thalassemia	Mild/moderate	9–12	>60	10–30	>3.5	<20
Hb SC	Mild/moderate	10–15	>50	0		0

Sickle cell trait (SCT) is found in 8% to 10% of African Americans. Sickle cell anemia occurs in 1 in 400 to 600 newborns. The disease is seen less commonly in the Hispanic, southern European, and Middle Eastern populations (1).

Hemoglobin electrophoresis provides rapid and accurate diagnosis of hemoglobinopathies. However, the sickle cell prep (Sickledex) can produce false-negative results before 4 and 6 months of age owing to the presence of normal maternal hemoglobin, and it also cannot differentiate between SCD with SCT.(4).Today, state-mandated newborn screening programs allow for early diagnosis of these disorders (5) Nevertheless, unexplained anemia in African American children should raise the suspicion of a hemoglobinopathy. The hemoglobin electrophoresis and HPLC identifies the various types of hemoglobin and allows for the differentiation of SCT and SCD.

Clinical symptoms may begin as early as 3 to 4 months of age, when significant amounts of hemoglobin S present. Early recognition and aggressive ED management can decrease the morbidity and mortality associated with these disorders. Long-term care is best provided by physicians familiar with the disease and its complications. SCD presentations generally fall into one of the six categories: (1) vaso-occulsive crisis, (2) dactylitis, (3) sepsis, (4) aplastic crisis, (5) acute splenic sequestration, and (6) ACS.

ACUTE PAINFUL VASO-OCCLUSIVE CRISIS

CLINICAL PRESENTATION

Acute painful vaso-occlusive (VOC) episodes are the most common manifestation of SCD and the most common reason for ED presentation and hospital admission (6). Pain is the result of tissue ischemia and infarction caused by micro vascular occlusion and may

be severe, unpredictable, and relentless. Precipitating factors include infection, dehydration, high altitude, and extremes of temperature. Often, however, no precipitating factor is identified (6).The frequency of such episodes increases with advancing age, alpha thalassemia trait, high hemoglobin concentration, high ferritin level, higher median tricuspid regurgitation jet velocity, lower parasympathetic activity and greater sympatho-vagal imbalance, and higher blood viscosity (7).The frequency of painful episodes is a marker of disease severity and correlates, ultimately, with increased mortality (6).

The average rate of painful crisis per patient is 0.8 episodes per year, although 1% of patients experience more than six episodes per year, and 5% of patients account for 33% of all episodes (8). Recent data has shown 17% having more than three episodes and a re-hospitalization rate of 33%.

The pain of VOC most often involves the lower back, chest, femoral shafts, hips, knees, and abdomen. In children, the hands, feet, fingers, and toes are more commonly involved. In individual patients, pain tends to recur in a limited number of sites (6). Given the propensity of symptoms involving the chest, abdomen, and extremities, the emergency physician must always consider other diagnosis in SCD patients presenting with acute pain such as ACS, septic arthritis, bone fractures, or acute surgical abdomen. In the absence of complications, physical examination in acute VOC is usually unremarkable which emphasize the need of thorough history and high index of suspicion for serious occult illness.

VOC is a medical emergency. Patients in acute pain presenting to the ED usually have exhausted all home care options and require parenteral opioid analgesia (9). There remains variability in the ED management of painful crisis, and barriers to optimal management persist (9). Implementation of a Clinical Practice Guideline (CPG) to manage VOC enables a standardized approach for the cost-effective care of patients with SCD (10). VOC usually vary in intensity and duration at different times. Painful crises are treated episodically in the ED by health-care providers with whom the patient has no established relationship. Patients often report severe pain but lack

objective findings, health professionals often fear iatrogenic opioid addiction, and patients may demonstrate behavior resulting from undertreated pain that is then perceived as drug-seeking in nature (6). Interestingly, it has been shown that although SCD patients receiving opioids may develop physiologic dependence and tolerance, the rate of addiction is no greater than in the general population.

ED MANAGEMENT

ED management has traditionally consisted of supplemental oxygen and fluids. There is no evidence that either therapy improves outcome in the nonhypoxic, euvolemic patient, and the chronic anemia and renal impairment that occurs in many patients with this condition puts them at risk of pulmonary edema if too vigorously resuscitated with isotonic fluid (11).

The mainstay of ED management is parenteral opioid analgesia (12). The intravenous route is preferred although the subcutaneous route can be used if venous access is difficult. The intramuscular route is not appropriate as this is painful and drug absorption is unpredictable. Morphine and hydromorphone are effective. Effective pain management requires some form of titration to effect pain relief, which means attempts should be made to objectify the severity of the patient's pain using a pain scale. One approach involves an initial bolus dose of morphine (Table 280.2) followed by repeated small boluses at intervals of 15 to 30 minutes until pain is relieved (12). Patients should be carefully observed for respiratory depression and hypotension. Monitoring of vital signs, oxygen saturation, intake and output should also be monitored. Pain relief is then maintained with bolus doses on a fixed schedule. If pain relief is maintained, the patient is discharged on an equianalgesic dose of an oral opioid until outpatient reassessment. If pain is not maintained after two to three bolus doses, hospital admission is required. Adjunctive medications such as antihistamines and antinauseants may be necessary to mitigate opioid side effects. Parenteral ketorolac cannot be routinely recommended; it does not consistently relieve pain and has potential for renal toxicity (11).

TABLE 280.2
Suggested Approach to Pain Control in Patients with Vaso-Occlusive Crisis

ED management of pain in VOC
Initial bolus morphine 0.1–0.15 mg/kg IV
1/4–1/2 of bolus dose q15–30 min until pain relief
Morphine bolus q2 hourly to maintain pain relief
If pain relief is maintained, discharge with oral analgesics and arrange for outpatient follow-up
If pain relief is not maintained, admit

The emergency physician must be aware of the role of hydroxyurea in VOC. Although not indicated in the management of the acute painful event, treatment with hydroxyurea has been shown to decrease the incidence of VOC by 44% and is indicated in patients experiencing more than three episodes per year.

DACTYLITIS (HAND&NDASH;FOOT SYNDROME)

CLINICAL PRESENTATION

The hand–foot syndrome commonly presents between 6 and 24 months of age in children with SCD. It is often the first manifestation and these children usually present with low-grade fever and swelling of hands or feet or both, secondary to infarction of the metacarpals and metatarsals. The children usually present with the irritability, inability to bear weight on the affected joint along with swollen and tender joint on examination. Hematologic values are usually unchanged. Radiographs at the outset show only soft-tissue swelling, but osteolytic and periosteal changes become evident 2 to 3 weeks after the onset of symptoms. This classic presentation must be differentiated from osteomyelitis (either unifocal or multifocal) and trauma.

ED MANAGEMENT

Therapy consists of hydration at 150% to 200% maintenance (with either oral or intravenous fluids) and pain management. Pain and

swelling commonly resolve in 2 to 5 days. As the patient ages the collateral vascular supply to these bones develops making recurrence uncommon, especially, after 2 years of age.

SEPSIS

CLINICAL PRESENTATION

In spite of current vaccination and prophylactic antibiotic regimens, sepsis is the leading cause of morbidity and mortality in SCD patients (1). These patients suffer from functional asplenia (occurring at age 5 months to 5 years) secondary to progressive splenic auto-infarction, resulting in deficient antibody production and impaired phagocytosis. SCD patients are, consequently, susceptible to potentially life-threatening infections by encapsulated organisms (Table 280.3) such as *Streptococcus pneumonia* which is the most common cause of sepsis and meningitis in children younger than 3 years old and carries a mortality rate of 20% to 50%. Bacterial meningitis and septicemia are 600 times more common in children with sickle cell anemia than in normal children (13).

TABLE 280.3
Various Microorganisms Causing Lethal Infections in Patients with SCD

Microorganism (Bacterial)	Infection	Remarks
Streptococcus pneumoniae	Septicemia	Common despite prophylaxis and vaccine
	Meningitis	Low frequency compared to pre-vaccine era
	Pneumonia	Rare except in children
	Septic arthritis	Uncommon
Haemophilus influenza type b	Septicemia	—
	Meningitis	—
	Pneumonia	Low frequency compared to pre-vaccine era
Salmonella species	Osteomyelitis	Most common cause of bone and joint infection
	Septicemia	—
Escherichia coli and other gram-negative enteric pathogens	Septicemia	Urinary tract infection
Staphylococcus aureus	Osteomyelitis	Uncommon
Mycoplasma pneumoniae	Pneumonia	Pleural effusions; multilobe involvement
Chlamydia pneumoniae	Pneumonia	—
Viral organisms		
Parvovirus B19	Aplastic crisis	Marked bone marrow suppression
Hepatitis viruses (A, B, and C)	Hepatitis	Hyperbilirubinemia

Vaccination and daily penicillin prophylaxis starting at 2 months of age have been shown to reduce the incidence of pneumococcal sepsis (14). The effectiveness of the 23-valent pneumococcal polysaccharide vaccine among children with SCD is 80% to 90%. Penicillin prophylaxis in children younger than 3 years is 125 mg orally twice daily (15) and 250 mg orally twice daily for ages 3 to 5 years. The role of prophylaxis after the age of 6 years remains controversial given concerns regarding the growing prevalence of penicillin resistance pneumococci.

Early recognition of a febrile episode and prompt administration of IV antibiotics can lower the risk of severe pneumococcal sepsis. However, resistant strains of pneumococcus have emerged, necessitating an alternative antibiotic regimen incorporating vancomycin (Table 280.4).

TABLE 280.4
Management of Sepsis in Patients with SCD

Evaluation
History: Immunization and penicillin prophylaxis
Labs: Complete blood count, electrolytes, Hgb S levels,
–Cultures (blood, urine, throat, cerebrospinal fluid) as indicated
–Chest X-ray
Treatment
IV Ceftriaxone 75 mg/kg
Add vancomycin 15 mg/kg if meningitis is suspected
Hydration

Haemophilus influenzae type b is the second most common organism responsible for sepsis in SCD patients. *H. influenzae* vaccine given during early infancy provides excellent protection against this organism.

Salmonellosis and osteomyelitis occur more commonly in patients with SCD than in normal children, probably secondary to infection of the infarcted bone (1). Osteomyelitis is typically caused by Salmonella and *Staphylococcus aureus.* There are now reported cases of rare fulminant infections with nontuberculous mycobacterium (16).

ED MANAGEMENT

The ED management of SCD patients presenting with fever (with or without an obvious focus of infection) includes administration of IV ceftriaxone (50–75 mg/kg per dose up to 2 g), after a complete blood count, reticulocyte count, and blood culture are obtained. Patients can be classified as low risk (age >1 year, well-appearing, white blood cell count between 5,000 and 30,000/cubic mm, temperature <104°F, absence of pulmonary infiltrates, and a reassuring Hb) or high risk. Low-risk patients can be managed in an outpatient setting with 24-hour follow-up. High-risk patients are admitted for inpatient treatment (17).

Children younger than 1 year of age with fever are typically admitted for intravenous antibiotics. Children with a temperature >103°F, toxic appearance, missed doses of prophylactic penicillin, respiratory distress, uncertain follow-up, previous episodes of severe

sepsis or meningitis and segmental/lobar infiltrates on chest X-ray should also be admitted. Older children with a temperature <103˚F and no focal source of infection may be discharged to home after obtaining appropriate cultures and receiving ceftriaxone, but reliable follow-up must be ensured.

APLASTIC CRISIS

CLINICAL PRESENTATION

To maintain baseline hemoglobin levels, bone marrow erythroid activity is increased in SCD patients (reticulocyte activity >10%). An aplastic crisis occurs when this increased erythropoietic activity is interrupted by various infections (such as parvovirus B19) causing acute cessation of RBC production. An aplastic crisis is characterized by a drop in hemoglobin, a low reticulocyte count (<1%), and a decrease in marrow activity. Parvovirus B19 accounts for 68% of episodes of aplastic crisis (18), followed by *S. pneumoniae,* Salmonella, and Epstein–Barr virus. Packed red blood cell transfusions may be necessary until erythroid production returns, usually within a few weeks. The patients with aplastic crises can present with fatigue, GITgastrointestinal symptoms, and signs of upper respiratory tract infections.

ED MANAGEMENT

Patients with aplastic crisis require close monitoring to avoid life-threatening anemia where the hematocrit falls to < 10% within a few days. By enlarge these patients do well with supportive treatment after a timely diagnosis. Hydroxyurea has been shown to reduce the occurrence of aplastic crisis.

ACUTE SPLENIC SEQUESTRATION

CLINICAL PRESENTATION

Splenic sequestration is a life-threatening condition seen in young children before the onset of splenic autoinfarction. Children with Hb

SS have an incidence of 30%, carrying a 15% mortality rate and often occur within the context of a viral illness. Over a period of hours, a significant portion of the circulating blood volume is sequestered in the spleen because of vaso-occlusion within the splenic vein. This usually occurs when a bacterial or viral infection is associated with a massive coinciodental intrasplenic trapping of erythrocytes. This sequestration of erythrocytes within the spleen contributes to a remarkable fall in hemoglobin levels. Patients may present with hypovolemia, pallor, massive splenomegaly, and occasionally shock and death.

ED MANAGEMENT

Treatment is aimed at sustaining blood volume until the condition spontaneously reverses, releasing the sequestered blood cells to free circulation. Careful monitoring and, often, a transfusion of 10 mL/kg of packed red blood cells may be required (18). Sequestration may recur in 50% of cases making splenectomy after resolution strongly recommended. Parents should be educated on how to palpate for an enlarged spleen, especially during viral illness, to promote early detection of this fulminant condition.

ACUTE CHEST SYNDROME

CLINICAL PRESENTATION

The ACS in SCD is a clinical syndrome with multiple etiologies sharing a common pathophysiologic endpoint of acute lung injury (19,20). ACS is defined by the presence of a new segmental pulmonary infiltrate on chest radiograph accompanied by at least *one* of the following clinical symptoms or signs: (a) temperature $>38.5^{\circ}C$, (b) chest pain, (c) cough, (d) wheezing, (e) tachypnea, or (g) worsening anemia (19).

The pathophysiology of acute lung injury in SCD is multifactorial, with a final common pathway of pulmonary micro-vascular obstruction, tissue hypoxia, ischemia, and infarction (19). Recurrent episodes of acute lung injury may lead to chronic restrictive lung disease (19,20). A large multicenter trial found the most common

causes of ACS to be related to fat embolism from infarcted bone marrow, respiratory infection, and isolated lung infarction. The most common pathogens identified in this study were chlamydia, mycoplasma, and respiratory viruses. Interestingly, the rate of fibrin thromboembolism is no greater in patients with SCD than in the general population, and thromboembolism is very difficult to distinguish from sickle vaso-occlusion by chest computed tomography scan or radionuclide perfusion scanning (19).

ACS is the leading cause of death among patients with SCD and the second leading cause of hospitalization (19). One-half of all patients with SCD will have one episode of ACS, and some patients will experience multiple events. One-half of all cases of ACS occur after hospitalization for an acute pain crisis. The peak incidence is between the ages of 2 and 4 (19). There is a higher incidence of ACS in those with Hb SS disease and in patients with higher baseline white blood cell counts. Patients with higher Hb F levels have a lower incidence of ACS, which may account for the lower incidence in patients younger than 2 years of age and in patients taking hydroxyurea.

The clinical presentation of ACS in the ED is variable and may mimic that of other chest syndromes in the general population, particularly bacterial pneumonia. It is important to be aware that the clinical course of ACS differs from that of the general population presenting with similar findings. Patients with ACS may present with a transient benign illness or may present in respiratory failure requiring intubation and mechanical ventilation. In one study, the average length of hospital admission was 10.5 days, and 13% of patients required mechanical ventilation (19). During hospitalization, 11% experienced neurologic symptoms, and 9% of those older than age 20 died. Factors predictive of a more severe course are age older than 20, pain in the arms and legs on presentation, platelet count $<200{,}000/\mu L$, and multilobar involvement or pleural effusion on chest radiograph. Clinical findings in ACS appear to be age dependent. Although fever is the most common presenting finding in all patients, children younger than 10 years of age are more likely to present with cough and wheezing, whereas adolescents and adults

more commonly present with chest and extremity pain. Bacteremia is more common in children with ACS, and *S. pneumoniae* is the most common isolate. Initial chest radiographs may be negative in nearly half of the cases. In children, upper and middle lobe infiltrates are more common, whereas adults are more likely to have isolated lower-lobe involvement and pleural effusions (19).

ED MANAGEMENT

The management of ACS is essentially supportive and aims to maintain alveolar ventilation and gas exchange and to prevent further pulmonary injury (Table 280.5). Patients should receive supplemental oxygen to maintain oxygen saturation >92% (19,20). Fluid deficits should be corrected with normal saline infusion, which is then changed to hypotonic fluid such as 5% dextrose in one-fourth normal saline at 1.5 times the maintenance requirement. Overaggressive hydration should be avoided to prevent pulmonary edema. Patients should receive prompt antibiotic therapy to cover the most common organisms identified in this syndrome, with consideration given to local sensitivity patterns. A respiratory quinolone alone, or a third- or fourth-generation cephalosporin in combination with a macrolide, should provide adequate coverage (19,20). Bronchodilators should be given, as all patients have been demonstrated to have some degree of airflow obstruction even in the absence of wheezing (19,20). Pain should be aggressively managed with parenteral opioids and incentive spirometry prescribed to prevent atelectasis since ventilation may be compromised by pain secondary to ischemia or infarction of ribs and/or thoracic vertebrae. The role of transfusion therapy in the ED management of patients with ACS is not clearly defined. However, red blood cell transfusion early in the course of ACS is the only treatment that has been shown to stabilize acute lung injury (5). Simple transfusion is indicated when there is a need to increase oxygen-carrying capacity with the objective of decreasing cardiac workload and improving patient comfort. Urgent exchange transfusion should be considered in patients with poor prognostic factors, where it may lead to rapid resolution of ACS and who are at risk for respiratory failure (19,20).

TABLE 280.5
ED Management of Acute Chest Syndrome

1. O_2 to keep SaO_2 >92%
2. IV D5:1/4 NS at 1.5× maintenance
3. Antibiotics
   Levofloxacin 500 mg IV or
   Ceftriaxone 2 g IV and
   Azithromycin 500 mg PO
4. Morphine IV titrated to pain relief
5. Salbutamol 2.5–5 mg q1–4h
6. Incentive spirometry
7. Simple or exchange transfusion
8. Admission

Patients with ACS are prone to rapidly deteriorating clinical courses and should be admitted.

CEREBROVASCULAR ACCIDENT

CLINICAL PRESENTATION

Patients with SCD suffer from neurologic injury with a spectrum ranging from silent cerebral infarcts (SCI) to overt strokes. SCI are the most common form of neuronal damage in toddlers (<4 years old), and the cumulative incidence increases until 14 years of age. Kinney et al. (21) identified 266 infants with SCD and followed them up for 14 years with a minimum of one magnetic resonance imaging MRI at 6 years or older and showed an incidence of 22% SCI in patients without overt stroke (21). These SCI infarcts result in progressive neuronal damage, resulting in lower intelligence and other neurocognitive defects. A history of seizure, leukocyte count $>11.8 \times 10^9$ and the presence of the Senegal-3 globin gene haplotype are associated with an increased risk of SCI. SCI is diagnosed on the basis of an abnormal MRI (focal 3-mm or larger area of abnormal signal intensity) with a normal neurologic examination result and without a history or physical findings suggestive of an overt stroke. No therapy has been established for the

treatment of SCI. Preliminary data from the STOP trial indicated that in patients with SCI and an elevated transcranial Doppler (TCD) ultrasound velocity measurement, blood transfusion resulted in a 100% relative risk reduction (Table 280.6) (15). Currently, a large trial funded by the National Institutes of Health is investigating the role of blood transfusion in patients with SCI and normal TCD measurements.

TABLE 280.6
Management of Stroke in Patients with SCD

Evaluation
–CBC, electrolytes, high S levels, sample for red cell antigens
–Urgent CT or MRI (identify thrombotic vs hemorrhagic infarction, cerebral aneurysm, and intracranial bleed)
Arteriography is not indicated as it can precipitate sickling crisis
Treatment
–1½–2 volume exchange transfusion to reduce Hgb S less 30%
–ICU admission
–Neurology and hematology consultations

CBC, complete blood count; CT, computed tomography; MRI, magnetic resonance imaging; ICU, intensive care unit.

Overt stroke occurs at a rate of 1 in 600 to 100,000 patient years, resulting in a prevalence of 10% by the age of 50 (22). In the younger child, the event is usually thrombotic; in the adolescent it may be hemorrhagic. Patients at increased risk for stroke include those with familial propensity, parvovirus infection, prior stroke or SCI, or increased TCD velocity measurement. Silent stroke is the strongest risk factor for overt stroke.

ED MANAGEMENT

In the ED, any untoward neurologic event in a sickle cell patient is considered a cerebrovascular accident until proven otherwise. Early recognition and aggressive treatment result in improved outcomes. Long-term treatment necessitates hypertransfusion for several years to reduce the 66% chance of a recurrent cerebrovascular accident

(18). Hydroxyurea therapy has also been shown to be effective for prevention of recurrent stroke in sickle cell patients.

PRIAPISM

CLINICAL PRESENTATION

Priapism is defined as a sustained, painful, and unwanted erection and is a well-recognized complication of SCD (23). It is an unpredictable and recurrent complication that has potentially devastating consequences for future erectile function and quality of life. At least one episode of priapism is described by 30% to 45% of adult patients with SCD, and it occurs most commonly in patients with HbSS disease. The mean age of occurrence is 12, and the mean duration of episodes is 125 minutes (23).

Priapism is believed to occur because of sickling and sludging of erythrocytes in the corpora cavernosa, with subsequent deoxygenation, acidosis, further sludging, increased intercavernosal pressure, penile ischemia, and, finally, fibrosis resulting in impotence (23). Episodes most commonly occur during sleep but may be triggered by sexual activity, alcohol, or drug use (23).

The emergency physician should document the time of episode onset and inquire about potential triggers. Physical examination reveals an erect penis with a soft glans. Priapism is a urologic emergency. There is a high risk of ischemic injury if symptoms continue beyond 4 hours (23). Urology consultation should thus be obtained early in the ED course.

ED MANAGEMENT

The goals of ED management are pain relief, resolution of erection, and preservation of future erectile function. All patients should receive parenteral opioid analgesia and may receive intravenous hypotonic fluids at 1.5 times the maintenance rate. Patients arriving in the ED whose episode has already lasted 4 hours require immediate urologic consultation with penile aspiration and irrigation using a dilute solution of epinephrine or phenylephrine (23). Patients who arrive earlier in an episode may receive a trial of oral vasoactive

agents such as terbutaline or pseudoephedrine (Table 280.7), which have been shown to be effective in pharmacologically induced priapism but have not been studied in SCD (23). Patients whose erections resolve in the ED should be educated on the importance of seeking early medical care if priapism recurs, of avoiding of triggers, and of following up with their primary care provider.

TABLE 280.7
ED Management of Priapism

1. IV D5:1/4 NS at 1.5 maintenance
2. Parenteral opioid analgesia
3. If >4 hours duration:
   - *Urgent* urology consultation
   - Cavernosal aspiration and irrigation
   - Exchange transfusion/surgical shunt in resistant/recurrent cases

   If <4 hours duration:
   - Trial of vasoactive agents
   - Terbutaline 2.5–5 mg PO
   - Pseudoephedrine <10 year: 30 mg PO >10 year: 60 mg PO
   - Urology consultation if persistent

KEY TESTING

- CBC
- Consider Type and Screen for patients likely to be transfused
- Reticulocyte count
- CXR when considering acute chest syndrome
- CT head for any alteration in mental status
- Pulse oximetry monitoring

CRITICAL INTERVENTIONS

- Prompt administration of antibiotics to all febrile sickle cell patients.
- Rapid titration of opioid analgesia for patients with acute vaso-occlusive crisis.

- Early recognition and aggressive management of hypoxia and hypoventilation in ACS.
- Immediate blood transfusion for aplastic and splenic sequestration crisis.
- Exchange transfusion in patients with cerebrovascular accidents and ACS.
- Emergent cavernosal aspiration in priapism of >4 hours duration.

Patients can be discharged from the ED if the child does not require supplemental oxygen is tolerating fluids orally, and has follow up with family or primary physician.

DISPOSITION

Patients with SCD are prone to a variety of complications and can rapidly deteriorate. ED physicians should be cautious in the disposition of these patients and maintain a low threshold for inpatient management. It is essential that the patient's primary care physician and hematologist be advised of the patient's emergency visit and consulted regarding the discharge plan.

Common Pitfalls

- Failure to appreciate the immunocompromised status of patients with SCD.
- Failure to recognize that symptoms may present as early as 3 to 4 months of age.
- Failure to recognize that the sickle prep is inaccurate before 4 to 6 months of age.
- Failure to consider a cerebrovascular accident when evaluating any acute neurologic event in a patient with SCD.
- Failure to consider aplastic crisis and acute splenic sequestration in the acutely anemic sickle cell patient.
- Failure to appreciate the severity of pain in acute VOC.
- Failure to appreciate the potential for rapid deterioration associated with ACS.
- Failure to ensure rapid urology consultation and cavernosal aspiration in the patient with priapism of more than 4 hours

duration.

CHAPTER 281

Urticarial, Maculopapular Lesions

Barry Gilmore and Rudy Kink

Urticarial and maculopapular lesions account for a large percentage of dermatologic complaints. Their prevalence is eclipsed only by the breadth and variety of pathology they represent, which ranges from allergic reactions to conditions such as measles and rubella. Although many presentations are benign, there are some where early identification may have a significant impact on infection control or require immediate treatment.

URTICARIA

Urticaria (hives) is a common skin condition affecting virtually all age groups but is more prevalent in children and young adults. It is estimated that 15% to 25% of the population will have an episode in their lifetime (1). Urticaria represents a vascular reaction of the skin characterized morphologically by transient, typically pruritic, red or white, smooth, elevated patches (wheals) which may change shape and location over time. Urticaria results from the release of histamine, bradykinin, leukotriene C4, prostaglandin D2, and other vasoactive agents released from basophils and mast cells. There is a transient extravasation of plasma into the superficial dermis, causing intense pruritus from the histamine release (2). This distinguishes urticaria from angioedema, which involves the deep dermis and results in deep tissue swelling and pain. The lesions may present in ring-like configurations or may coalesce over larger areas.

Urticaria can be classified by the duration of symptoms. Acute urticaria is defined by symptoms lasting less than 6 weeks; chronic urticaria lasts more than 6 weeks. Chronic urticaria typically requires further evaluation to rule out an underlying systemic medical condition. The causes of urticarial can be divided into several broad categories (see Table 281.1).

TABLE 281.1
Classification of Urticaria

Physical	Insects
Cholinergic	Inhalants
Dermatographism	Drugs
Pressure	Transfusion related
Cold	PUPP[a]
Solar	Idiopathic
Vibratory	Urticarias in chronic disease
Aquagenic	Systemic vasculitis/collagen vascular disease/malignancy
Heat	Infections
Adrenergic	Genetic
Contact	
Food	

[a]PUPP, pruritic urticarial papules and plaques.

Clinical Presentation

A key feature is their polymorphic appearance and waxing and waning of individual lesions. Dermatographism (exaggerated triple response of Lewis) may also be noted; wheals occur within 10 minutes of moderate stroking and fade by 30 minutes.

There are many identified triggers of urticaria; the more common ones are summarized in Table 281.2. Typical triggers include foods, medications, infections (both viral and bacterial), environmental factors, latex, cold, heat, emotional stress, pregnancy, and exercise (3).

TABLE 281.2
Agents Known to Cause Urticaria

- Medications
  - ACEi
  - Anesthetic muscle relaxants (i.e., succinylcholine)
  - Narcotics
  - Penicillins
  - Cephalosporins
  - Sulfas
  - Diuretics
  - Aspirin
  - NSAIDs
  - Iodides
  - Bromides
  - Quinidine
  - Chloroquine
  - Vancomycin
  - Isoniazid
  - Antiepileptic drugs
- Infections
  - Viral
  - Amebiasis
  - Malaria
- Foods
  - Shellfish
  - Eggs
  - Cheese
  - Chocolate
  - Nuts
  - Berries
- Environment
  - Extremes of temperature
  - Dander
  - Dust
  - Molds
  - Water
- Pregnancy
- Contact
  - Nickel
  - Latex
  - Nail polish
  - Chemicals
- Exercise
- IV dye/contrast

ACEi, NSAID, nonsteroidal anti-inflammatory drug.

Medications are a significant cause of urticarial reactions, which tend to start as macules and papules on the trunk and extremities and spread outward. The onset may be 1 to 2 weeks following the start of a new medication but can occur much sooner if there have been previous exposures. Penicillin, cefaclor, amoxicillin, and aspirin are most frequently incriminated. Individuals who are aspirin intolerant may see an onset of symptoms with 15 minutes of ingestion, or after a delay of as long as 20 hours. These patients are also likely to have flushing, rhinorrhea, wheezing, and increased bronchial secretions (4,5).

Food allergies account for about 20% of cases of acute urticaria and are mediated by IgE-specific food proteins. The most common offending foods in adults are shellfish and nuts, whereas in children they tend to be peanuts, nuts, eggs, wheat, soy, and shellfish. The onset of symptoms may be within minutes of ingestion but can be delayed by several hours. A less common cause is scombroid fish poisoning caused by the ingestion of heat-stable toxins found in certain partially spoiled dark-meat fish such as tuna, salmon,

swordfish, and bluefish. Bacterial decomposition of histidine produces histamine that can induce nonwheal urticaria as well as other allergic responses (4,5).

Infections may be associated with urticaria, but less commonly so than other etiologies; in adults, when this occurs there tends to be an association with chronic urticaria. Children, however, may have hive-like rashes associated with the first 3 to 5 days of a viral illness and resolving as the infection clears. Urticaria has also been associated with hepatitis, infectious mononucleosis, herpes simplex, streptococcal infections, and parasitic infections (4,5).

Contact urticaria represents a reaction to a substance that comes in contact with an individual's skin. A multitude of agents have been found to trigger such a reaction, including metals, hair and beauty products, and foods.

In the healthcare setting, latex allergy has become a more commonly identified cause. Sensitized patients can progress very rapidly from a local reaction to angioedema and life-threatening anaphylaxis. Furthermore, patients with chronic medical conditions have a higher incidence. Thus, many institutions and offices have moved completely away from all latex-containing products.

Physical causes of urticaria are less common and are identified through a careful history and physical examination. *Dermatographism,* a reaction of the skin secondary to moderately firm stroking of the skin, comes on quickly (<10 minutes) and is usually gone within 30 minutes. *Pressure urticaria,* because of sustained contact, is characterized by localized pain and pruritus. Although the onset is typically delayed (6 to 72 hours), the location of the lesions is often a helpful clue in establishing the clinical connection. *Cold urticaria* is caused by exposure of skin to extreme cold, damp, and/or windy conditions and has an onset within minutes. Severe reactions resulting in massive histamine release have been reported with swimming in cold water. When an ice cube is placed on the forearm, a distinct hive may develop, helping to make the diagnosis at least in its more severe forms. Standard antihistamines show little effect, although improvement has been reported with cyproheptadine, doxepin, and ketotifen. Cold urticaria tends to affect 18 to 25 year

olds and may last for 5 to 6 years. There is also a rare hereditary form with delayed onset involving the entire body. *Cholinergic or stress urticaria* is triggered by any stimulus that causes an increased core temperature; the lesions are small, pruritic, and generally short lived (6). *Solar urticaria* occurs on areas exposed to ultraviolet or visible light; the onset is within minutes and wanes rapidly (1 to 3 hours) when the skin is no longer exposed (6). Miscellaneous types of urticaria include aquagenic (water exposure), vibratory, and those caused by insect bites and blood transfusions. Urticaria associated with blood transfusions has an incidence of 1% to 3%. This is not a transfusion reaction but an antibody-mediated response to the donor's plasma; they respond well to antihistamines.

Pruritic urticarial papules and plaques of pregnancy (PUPP) is a hive-like rash that affects some women during their pregnancy. It typically starts on the abdomen and spreads peripherally to the extremities. Although irritating, it is not considered a threat to mother or fetus.

Other systemic conditions are more commonly associated with chronic urticarial. These include malignancies (lymphoma, chronic lymphocytic leukemia), collagen vascular diseases, cryoglobulinemia, serum sickness, C1 esterase inhibitor deficiency, and hypo- and hyperthyroidism.

Differential Diagnosis

Initially it is critical to recognize developing anaphylactic shock with bronchospasm and progressive cardiovascular collapse (3,7). If anaphylaxis is not an issue, narrowing down the diagnosis is based on a detailed history and physical examination. Urticarial lesions can be confused with a number of common conditions listed in Table 281.3.

TABLE 281.3
Urticaria Differential Diagnosis

Anaphylactic Shock	Respiratory distress and CV collapse
Angioedema	Deep tissue swelling, mucous membrane involvement, abdominal symptoms
Atopic dermatitis[a]	Scaly, more maculopapular
Bullous pemphigoid[a]	Older adults, progresses to blistering
Contact dermatitis[a]	Areas of contact, popular, erythematous, vesiculation can occur
Cutaneous vasculitis[a]	Lesions >72 h
Dermatitis herpetiformis[a]	Papulovesicular lesions, extensor surfaces, associated with gluten intolerance
Erythema marginatum	Raised ring like lesions, extensor surfaces, spares face, wax and wane for months
Erythema multiforme[a]	Target lesions, long lasting, +/– Fever
Henoch–Schonlein purpura	Purpuric, lower extremities and buttocks, systemic symptoms
Juvenile arthritis	Salmon colored rash, typically on trunk, fever, fatigue, joint pain/swelling
Mastocytosis[a]	Dark brown, fixed lesions, fatigue, abdominal pain, nausea/vomiting
Morbilliform drug reactions[a]	Medication, more maculopapular
Pityriasis rosea (early lesions)	Herald patch, "Christmas tree" distribution, lasts weeks
Serum sickness	1–2 wks delayed onset, fever, arthralgias
Urticarial vasculitis	Painful, lesions last 1–2 days, purpuric, residual hyperpigmentation
Viral exanthemas	Fever, prodrome, specific lesions last days (do not come and go)

[a]Typically pruritic

ED Evaluation

Life-threatening conditions such as anaphylactic shock or critical angioedema must be ruled out early in any evaluation of urticaria. Once this has been done, a careful history and physical examination should be performed. The physical examination should note any signs or symptoms of upper airway involvement, including tongue swelling, stridor, or wheezing. The skin and extremity examination should discriminate between deep tissue edema suggesting angioedema urticaria, which is more superficial in nature.

In addition to a complete review of symptoms, clinicians must obtain a detailed history focusing on timing, onset, and progression of symptoms. The exposure history should focus on potential environmental agents, foods, medications, recent illnesses, and any past or family history of previous similar episodes. Often this information, along with the size, shape, location, and progression of

the lesions, can focus the evaluation and identify potential triggers. In the majority of cases, the trigger or underlying cause is never specifically identified.

Detailed laboratory evaluation is not warranted unless an underlying systemic condition is being considered, for example, when symptoms have been going on for 6 weeks (chronic urticaria). In this situation, current guidelines suggest a baseline CBC, liver function tests, erythrocyte sedimentation rate, urinalysis, and possibly TSH.

KEY TESTING

For chronic urticaria:
- CBC, ESR, LFTs, UA, and TSH

For acute urticaria:
- No specific testing

ED Management

Treatment is centered on removing possible offending agents and treating acute symptoms with H1 (histamine) blockers. The first-generation agents (diphenhydramine, hydroxyzine, chlorpheniramine, and cyproheptadine) have been used for quick relief of associated itching but have other side effects (sedation, dry mouth, confusion, trouble concentrating) that may be problematic for pediatric patients. The second-generation antihistamines (loratadine, desloratadine, fexofenadine, cetirizine, and levocetirizine) are now recommended as initial treatment options because of their less sedating properties as well as once-daily dosing. A mixture of first- and second-generation agents can be considered based on the patient's symptoms (3,8).

Adding an H2 blocker (cimetidine, famotidine, or ranitidine) has shown some mild benefit for the acute symptoms. A short course of steroids (oral prednisone at 0.5 mg to 1 mg/kg per day given for 3 to 7 days with a taper) may be helpful for those with significant symptoms or to help accelerating improvement, but data on effectiveness is limited (Table 281.4).

TABLE 281.4
Treatment of Urticaria

Class	Medication	Adult Dosing	Pediatric Dosing	Considerations
H1 blockers First generation	Diphenhydramine (Benadryl)	25–50 mg PO/IM/IV q6h	1 mg/kg PO Q6h	Sedating, avoid with MAOI's
	Hydroxyzine (Vistaril)	25–100 mg PO/IM QID	0.5 mg–1 mg/kg/dose IM q4–6h 2 mg/kg/24 h PO divided tid	Sedating, No IV
	Cyproheptadine (Periactin)	4 mg PO tid	0.25 mg/kg divided tid	Sedating
	Chlorpheniramine	4 mg PO q4h	6–11 y/o 2 mg po q4–6h (max 12 mg/day) > 12 adult dosing	Sedating
Second generation[a]	Cetirizine (Zyrtec)	5–10 mg PO qd	2–5 y/o 2.5–5 mg PO qd >6 y/o 5–10 mg PO qd	Chewable Tabs, Nonsedating
	Fexofenadine (Allegra)	180 mg PO qd	6 m–2y/0 15 mg PO bid 2–11y/o 30 mg BID >12 y/o adult dosing	Nonsedating, do not give with fruit juice, renal dosing
	Loratadine (Claritin)	10 mg PO qd	2–5 y/o 5 mg PO qd >6 y/o adult dosing	Nonsedating renal and hepatic dosing
Corticosteroids	Prednisone	40–60 mg PO qd < 6 day no taper needed	1–2 mg/kg divided bid	Caution in diabetics
	Methylprednisolone (Solu-Medrol)	125 mg IV/IM	0.5–2 mg/kg, IV/IM/PO (max 60 mg)	Caution in diabetics
	Hydrocortisone	100–500 mg IV	5–10 mg/kg IV (max 500 mg)	Caution in diabetics
H2 blockers	Cimetidine (Tagment)	400 mg PO qd 300 mg IV/IM qd	Infants 10–20 mg/kg/day PO/IM/IV divided q6–12h Children 20–40 mg/kg/day PO/IM/IV divided q6h	Use with H1 blockers
	Ranitidine (Zantac)	50 mg IV/IM or 150 mg PO bid	0.5 mg/kg/day PO/IV divided q6–12h	Use with H1 blockers
	Famotidine (Pepcid)	20 mg PO/IV qd/bid	1–2 mg/kg/day PO/IV divided bid (max 40 mg) Start with 1 mg/kg	Use with H1 blockers
Leukotrienes	Montelukast (Singular)	10 mg PO qd	6–14 y 5 mg PO qd >15 y adult dosing	Use with H1 for chronic/cold urticaria
	Zafirlukast (Accolate)	20 mg PO bid	5–11 y 10 mg PO bid >12 y adult dosing	Use with H1 for chronic /cold urticaria, caution with hepatic impairment

[a]Chronic urticaria may consider 2–4 × standard dose

Treatment of chronic urticaria occurs over a period of weeks. The initial treatment is the same as for acute urticaria, concentrating on the second-generation antihistamines at standard doses. If there is no improvement by 2 weeks, doubling or quadrupling the dose is suggested. If symptoms persist after another 1 to 4 weeks, switching agents, or adding a first-generation medication, H2 blocker, leukotriene antagonist, or brief steroid burst may be warranted. Referral to a dermatologist should be strongly considered (3,8).

CRITICAL INTERVENTIONS

- Epinephrine (SC/IM), antihistamines, steroids, and albuterol for life-threatening urticaria accompanied by cardiovascular collapse, bronchospasm, or laryngeal edema.
- Antihistamines are the initial treatment of urticaria.

Disposition

Most patients can be discharged home if they have acute uncomplicated urticaria that has responded to treatment. An observation period of 2 to 6 hours has been suggested, and most patients respond within 2 hours of treatment. Patients with rebound symptoms, anaphylaxis, hypotension, or airway swelling should be admitted for close observation. Antihistamines (H1 or H2 blockers) should be continued for 2 to 5 days and steroids, if used, for 5 to 7 days.

MACULOPAPULAR RASHES

Maculopapular exanthems comprise both flat discolored areas of skin and papules; these rashes often consist of large red areas with small confluent bumps (Table 281.5).

TABLE 281.5
Features of Selected Diseases with Maculopapular Eruptions

Disease	Age Most Affected	Typical Season	Type/Distribution of Lesions	Associated Signs and Symptoms	Complications
Measles	Children, young adults	Winter, spring	Skin—Purple-red maculopapules spreading from hairline down, confluent on face and neck oral mucosa—Koplik spots	Prodrome of high fever, coryza, cough, conjunctivitis	Common: Otitis media, pneumonia Rare: Encephalitis, laryngotracheitis
Rubella	Children, young adults	Winter, spring	Skin: Discrete, pink-red maculopapules spreading from face down Soft palate: Forchheimer spots	Children: Lymphadenopathy, mild fever Adolescent/adult: Febrile prodrome, joint pains	Common: Arthritis in older patients Very rare: Encephalitis, purpura
Erythema infectiosum	2–12 year	Late winter, spring	"Slapped-cheek" malar rash which spreads to the trunk and extremities	Asymptomatic or nonspecific illness (fever, chills, myalgias, malaise and headache)	Rare: Arthritis (especially in adults), hemolytic anemia, encephalitis, fetal loss
Scarlet fever	3–12 year	Winter, spring	Skin: Face flushed with circumoral pallor, trunk/extremities with "sandpapery," blanching pinpoint red rash most prominent in creases, Pastia lines Mucosal-pharyngitis/tonsillitis, palatal, petechiae, strawberry tongue	Fever, sore throat, vomiting, headache, abdominal pain, tender anterior cervical nodes	Early: Otitis media, peritonsillitis, cervical adenitis, sinusitis Late: Rheumatic fever, glomerulonephritis
Staphylococcal scalded Skin	Early childhood before age 5 year or immunocompromised adults or those with renal insufficiency	Year-round	Bullae formation and diffuse desquamation often resulting from hematologic spread of toxins, Nikolsky sign	Fever, malaise and general symptoms of upper respiratory tract infection	Skin desquamation with resulting hypovolemia, hypothermia, and secondary infection

Measles

Measles is a highly contagious disease caused by an RNA paramyxovirus. It is spread by direct droplet contact; the incubation

period is 6 to 19 days, with a median of 13 days. Patients are infectious from 1 to 2 days prior to the onset of the illness until 4 days after the rash appears. Natural measles infection allows for lifelong immunity, and measles vaccination is highly protective against the infection. There have been recent outbreaks of measles because of decreased vaccination rates. In 2011, a large measles outbreak occurred in Quebec, Canada, and in the United States (9,10). Of the 222 cases of measles reported in the United States, 85% were unimmunized individuals (10).

ED Evaluation and Management

Measles initially presents with 3 to 5 days of fever followed by cough, coryza, and conjunctivitis; collectively known as the "3Cs." The exanthem phase of infection is marked by the appearance of discreet 1 to 3 mm white plaques (Koplik spots) on the erythematous mucous membranes around the lower premolar area (Fig. 281.1). Other symptoms include headache, malaise, and decreased appetite.

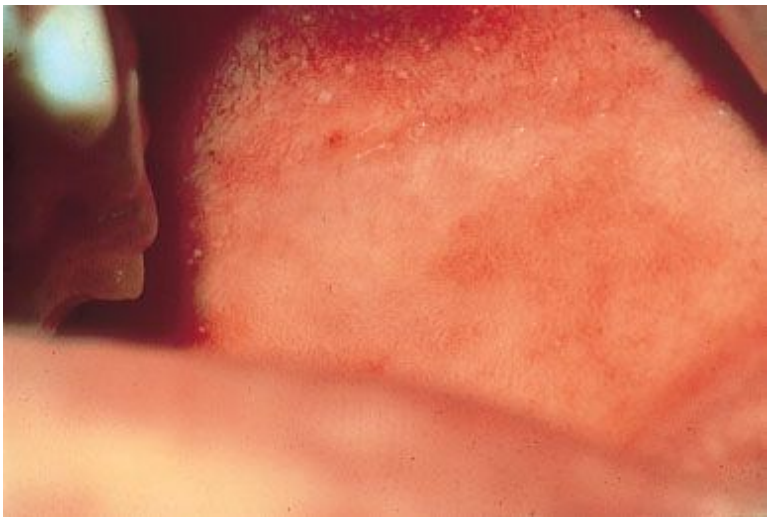

FIGURE 281.1 Koplik spots. (The Wellcome Trust, National Medical Slide Bank, London, UK.)

The viral exanthema usually appears 3 to 5 days after fever onset and is a blanching maculopapular rash starting around the hairline and progressing caudally to include the extremities; palms and soles are rarely affected (Fig. 281.2). The rash typically fades after 3 to 4

days, leaving a brown discoloration and desquamation. There is complete resolution by day 10 (11).

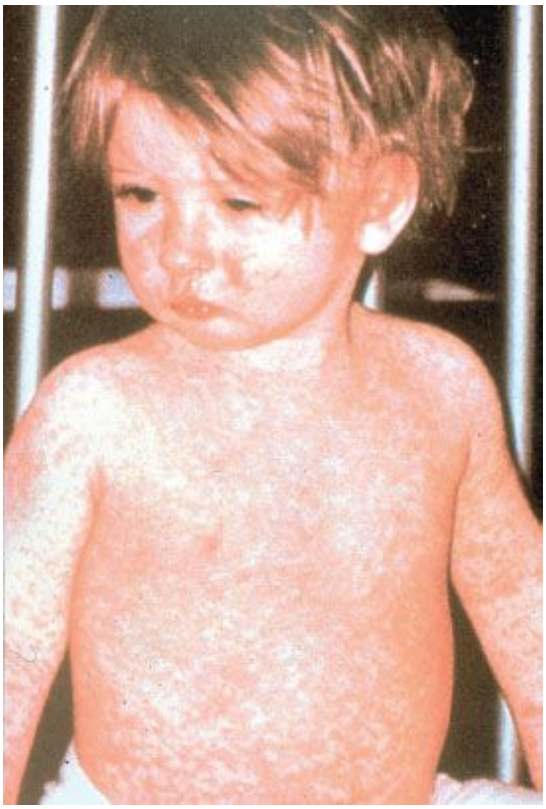

FIGURE 281.2 Measles. Morbilliform rash of measles. (Photo courtesy of Centers for Disease Control and Prevention.)

Measles can affect multiple organ systems, including pulmonary, neurologic, gastrointestinal, and cardiac. These complications can be life threatening. In children, otitis media, croup, bronchopneumonia, and diarrhea are commonly reported. Complications such as acute encephalitis, acute disseminated encephalomyelitis, and severe pneumonia are rare but may be life threatening. Other complications include myocarditis, pericarditis, hepatitis, Stevens–Johnson syndrome, appendicitis, and subacute sclerosing panencephalitis. The latter is a degenerative disease of the central nervous system caused by a mutant form of the measles virus. It occurs 2 to 10 years after the initial infection and is characterized by behavioral changes, seizures, intellectual decline, memory loss, and eventually death for the majority of patients (12).

The differential diagnosis of a maculopapular rash with fever includes mononucleosis, pityriasis rosea, Rocky Mountain spotted fever, syphilis, drug eruption often caused by penicillin, nonsteroidal anti-inflammatory drugs or phenytoin, as well as reactive conditions such as urticaria, erythema multiforme, and Kawasaki disease.

The treatment of measles is primarily supportive. A Cochrane review of randomized trials on the use of vitamin A concluded there was no overall significant reduction in mortality, but there was evidence that two doses were associated with a reduced risk of mortality and pneumonia-specific mortality in children under the age of 2 years. For those with secondary bacterial infection, appropriate antibiotic directed therapy is indicated (13). Patients presenting to the emergency department who are suspected of having measles should immediately be placed in isolation to decrease exposure of other patients. At risk patients, including infants, immunocompromised individuals, and pregnant women exposed to measles, can receive immunoglobulin intramuscular injections up to 6 days post-exposure. The dosage is 0.25 mL/kg IM or 0.5 mL/kg (maximum, 15 mL) for immunocompromised patients (14).

Rubella

Rubella (German measles or third disease) is caused by an RNA Ribivirus, belonging to the Togavirus family. It is spread by direct contact or droplets from nasopharyngeal secretions of an infected individual and can also be transplacentally transmitted to the fetus, with potentially serious consequences. The infection in children is typically mild and can even be asymptomatic. Infected individuals are contagious from a few days before rash onset to 7 days after rash onset. Infants who acquired rubella prenatally can become reservoirs and spread the virus for up to a year after birth (15).

ED Evaluation and Management

Patients with rubella have a low-grade fever, an erythematous maculopapular rash, and generalized lymphadenopathy. The rash typically starts on the face and spreads caudally to the extremities and lasts approximately 1 to 5 days. Infected patients can also have

conjunctivitis and/or Forschheimer spots (a viral exanthem occurring on the soft palate as erythematous areas with petechial macules). Symptoms in adolescents and adults include malaise, headache, pharyngitis, conjunctivitis, cough, coryza, and arthalgias. Adolescent females may experience monoarticular arthritis or arthalgias involving the fingers, wrists, and knees. Rare complications include encephalitis and thrombocytopenia (Fig. 281.3).

FIGURE 281.3 Rubella. Maculopapular rash of rubella. (From Goodheart HP. *Goodheart's Photoguide of Common Skin Disorders.* 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003.)

The fetus is particularly vulnerable to rubella infection. The earlier in the pregnancy the gravid patient is exposed, the more severe the infection is for the fetus. Structural defects typically occur if the fetus is exposed to rubella prior to 16 weeks of gestational age (16,17). Defects associated with congenital rubella involve the eye (congenital glaucoma, cataracts, and retinopathy), the brain (mental retardation, meningoencephalitis, and behavioral problems), the

heart (pulmonary stenosis, patent ductus arteriosus), the ears (sensorineural impairment), and the skin (purpuric skin lesions, blueberry muffin appearance) along with growth retardation, thrombocytopenia, hepatosplenomegaly, and bone disease (18) (Fig. 281.4).

FIGURE 281.4 Congenital rubella. Blueberry muffin rash of congenital rubella. (Photo courtesy of Centers for Disease Control and Prevention.)

Postnatal rubella infection is typically a mild infection requiring only supportive care including antihistamines for itching and nonsteroidal anti-inflammatory drugs for arthritis. Because rubella can cause devastating effects to fetuses, rapid diagnosis is critical if the patient is pregnant. If a pregnant woman is exposed to the virus, rubella antibodies should be obtained. If negative, antibodies should be obtained again in 2 to 3 weeks, and again 6 weeks post-exposure. Increases in antibody titers indicate a recent infection. Immunoglobulin (0.55 mL/kg IM) may be given, but it does not

guarantee prevention of fetal infection (19). Patients diagnosed with rubella infection should be placed on droplet precautions and be excused from school or daycare for 7 days from the time the rash started.

Roseola Infantum

Roseola (exanthem subitum or sixth disease) typically occurs in children between the ages of 6 months and 2 years and presents 3 to 5 days of high fever and then develops a morbilliform rash (20). The most common cause of roseola infantum is HHV-6, which is a double-stranded DNA human herpes virus. HHV-7 is a less frequent cause. HHV-6 has been associated with febrile seizures in 10% to 15% of patients (21). The majority of patients who have HHV-6 infections present with a fever, but they can have respiratory or gastrointestinal symptoms as well.

ED Evaluation and Management

Though roseola is a common infection, only 20% of patients present with the classic symptoms. Other symptoms of HHV-6 infection include malaise, palpebral conjunctivitis, uvula palatoglossal junctional macules or ulcers (sometimes called Nagayama spots), upper and lower respiratory symptoms, vomiting, diarrhea, and a bulging fontanelle. The rash is characterized by rose-pink macules or maculopapules that occur mainly on the trunk and neck and then may spread to the rest of the body (Fig. 281.5). The rash lasts approximately 1 week (22). The rash is similar to that caused by Epstein–Barr virus, adenovirus, parvovirus B-19, and other viral illnesses. The diagnosis is largely clinical.

FIGURE 281.5 Roseola. Maculopapular rash of roseola. (From Goodheart HP. *Goodheart's Photoguide of Common Skin Disorders.* 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003.)

Typically the infection is self-limited and resolves uneventfully. Rare complications include encephalitis, fulminant hepatitis, thrombocytopenia, and hepatosplenomegaly (22). Infants and children presenting with fever and bulging fontanelle are often evaluated for meningitis. Supportive care includes fever management and encouraging adequate hydration.

Erythema Infectiosum

Erythema infectiosum (fifth disease) is a common infection caused by human parvovirus B19 and seen predominantly in children ages 5 to 15 years (Fig. 281.6) (23,24).

FIGURE 281.6 Erythema infectiosum. "Slapped Cheeks" with perioral pallor. (From Goodheart HP. *Goodheart's Photoguide of Common Skin Disorders.* 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003.)

It was first discovered in 1975 and associated with the clinical disease in 1981. There are now three identified genotypes, with the first two found in Western countries and the third in sub-Saharan Africa and South America (25). It is normally transmitted via respiratory droplets but can also be transmitted via blood product transfusion, bone marrow and organ transplantation, and vertically from mother to fetus. It begins with a nonspecific illness consisting of low-grade fever, chills, myalgias, malaise, and headache, which is followed by a characteristic exanthem within 7 to 10 days. The contagious stage occurs approximately a week before the onset of rash.

The exanthem initially is an erythematous, raised rash over the malar areas of the face (giving a "slapped cheek" appearance) with associated circumoral pallor. It fades within 3 to 5 days. This is followed by a lacy, often pruritic rash occurring on the trunk, which in turn spreads peripherally to involve the buttocks and extremities (Fig. 281.7) (26). The rash can later recur when provoked by sunlight, heat and other environmental changes, exercise or emotion. Outbreaks tend to occur in school-age children but have been described in adults. The rash is not a feature of the disease in adults,

in whom it may present as acute arthritis and edema, primarily of the small joints (27). In children, in addition to the rash there may be other clinical manifestations, including arthropathy and a transient aplastic episode that is seen most often in patients with hemolytic anemia, hemoglobinopathies, or other abnormalities in red cell production or structure.

FIGURE 281.7 Erythema infectiosum. "Lacy Rash" of erythema infectiosum. (From Goodheart HP. *Goodheart's Photoguide of Common Skin Disorders.* 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003.)

ED Evaluation and Management

In an otherwise healthy patient, only supportive care is necessary (23,24). Laboratory testing is not indicated unless there is a concern for aplastic anemia or exposure in pregnancy. Patients with clinical hematologic effects such as an aplastic episode may require blood transfusions; immunocompromised patients may benefit from immune globulin intravenous infusion. Isolated pleural and pericardial effusions, intrauterine growth retardation, and fetal hydrops can contribute to fetal demise in 2% to 6% of cases of parvovirus B19 infection during pregnancy (especially in the second trimester). Pregnant healthcare workers should be advised of the

potential fetal risks and should adhere to strict infection control measures to avoid exposure to respiratory tract secretions and blood from infected patients.

Differential Diagnosis

The differential diagnosis includes measles, roseola, hepatitis, Epstein–Barr virus, and other viral exanthems; scarlet fever; Lyme disease; drug eruption; allergic hypersensitivity reaction; acute rheumatic fever; and other rheumatologic disorders.

Scarlet Fever

Scarlet fever (scarlatina) is caused by the pyrogenic exotoxins produced by anaerobic group A beta hemolytic streptococci (GABHS) (28,29), one of the many manifestations of GABHS. The spectrum of presentation is broad and includes pharyngitis, sinusitis, pneumonia, meningitis, superficial skin infection (such as perianal dermatitis), and, less commonly, immune-mediated sequelae such as rheumatic fever, Sydenham chorea, neuropsychiatric disorders (PANDAS), reactive arthritis, and glomerulonephritis. Classically, patients present with fever, sore throat, headache, and vomiting. The typical "sandpaper" rash begins within 1 to 2 days of the onset of fever.

This nonpruritic micropapular and macular rash begins on the lower face, chest, and axilla and spreads in the next 6 hours to involve the rest of the trunk and extremities. It often resolves in 1 week and is followed by desquamation 7 to 10 days later, with the hands and feet being most noticeably affected (Fig. 281.8). Other distinguishing features include circumoral pallor, increased intensity of erythema in the skin folds of the axilla and groin, and transverse streaks in the skin folds known as Pastia lines. The characteristic oropharyngeal findings are an erythematous pharynx and tonsillar exudates. The palate has scattered petechial and punctuate lesions. In addition, there is initially a "white strawberry tongue," which evolves into a "red strawberry tongue" by day 4 or 5.

FIGURE 281.8 Scarlet fever. Desquamation of hands from scarlet fever. (From Goodheart HP. *Goodheart's Photoguide of Common Skin Disorders.* 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003.)

Differential Diagnosis

The differential diagnosis of scarlet fever includes viral syndromes such as Epstein–Barr virus, measles, and rubella. Bacterial infections including staphylococcal infections, Hemophilus influenzae, and secondary syphilis, as well as toxic shock syndrome, drug hypersensitivity reactions, juvenile rheumatoid arthritis, Kawasaki's disease, and acute systemic lupus erythematous, should also be considered.

ED Evaluation and Management

The diagnosis of scarlet fever is based on the clinical examination. A rapid streptococcal antigen test may be ordered to confirm or document the cause of infection if needed. The treatment of choice is oral penicillin V or intramuscular benzathine penicillin (30). Amoxicillin is also equally effective. Macrolides can be used for penicillin-allergic patients and cephalosporins are an alternative unless there is a history of an immediate or Type 1 hypersensitivity reaction, in which case clindamycin should be used. Antibiotic treatment can help improve fever and constitutional symptoms

within 2 days and can almost eliminate the risk of acute rheumatic fever. However, the role of proper antimicrobial therapy in preventing acute post-streptococcal glomerulonephritis remains uncertain.

Staphylococcal Scalded Skin Syndrome

Staphylococcal scalded skin syndrome (SSSS) is caused by the acute exfoliatins, exotoxin A and B, produced by catalase-positive *Staphylococcus aureus* (30,31). Through hematogenous spread, these epidermolytic toxins act at distant skin sites, leading to a separation of the intraepidermal layers, formation of bullae, and diffuse desquamation. In addition to exfoliatins, *Staph. aureus* can produce coagulase and clumping factor, as well as other destructive tissue factors (30). Coagulase causes the clotting of plasma through interaction with fibrinogen, facilitating abscess formation, and clumping factor induces clumping of the organisms, which prevents effective phagocytosis by the host's immune system.

Typically, *Staph. aureus* colonizes the skin and nasal passages of healthy hosts without untoward effect. Young children typically cannot mount an effective immune response or metabolize and excrete toxins related to *Staph. aureus,* and thus SSSS is usually a disease of early childhood (usually before age 5). Generalized exfoliation has also been known as Ritter disease, and in neonates it is known as pemphigus neonatorum. SSSS in children begins with malaise, fever, and upper respiratory tract symptoms. The exfoliatin-induced rash follows, with generalized and sometimes tender erythema worse in the flexures but sparing the mucous membranes. Classically, shearing of the upper epidermal layers with gentle pressure (Nikolsky sign) is observed and is followed by bullae formation and diffuse desquamation (Figs. 281.9 and 281.10).

FIGURE 281.9 Nikolsky sign. (From Fleisher GR, Ludwig S, Baskin MN. *Atlas of Pediatric Emergency Medicine.* Philadelphia, PA: Lippincott Williams & Wilkins; 2004.)

FIGURE 281.10 Staph scalded skin. Bullae and diffuse desquamation of skin. (From Avery GB, Fletcher MA, MacDonald MG. *Neonatology:*

Pathophysiology and Management of the Newborn. 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999.)

Differential Diagnosis

The differential diagnosis of SSSS includes Kawasaki disease, epidermolysis bullosa, toxic shock syndrome, impetigo, scarlet fever, toxic epidermal necrolysis (TEN), and graft-versus-host disease. TEN is often caused by an immunologic reaction to specific viruses, mycoplasma, or drugs. Unlike SSSS, TEN almost always involves the mucous membranes, and the Nikolsky sign is only present in damaged areas of skin. TEN also causes full thickness skin splitting at the dermo-epidermal junction, in contrast to SSSS which causes splitting within the granular layer of the epidermis without necrosis.

ED Evaluation and Management

Microbial analysis of material obtained from skin lesions or bacterial foci such as abscesses can provide evidence of infection and guide antimicrobial therapy. *Staph. aureus* is never normally isolated from otherwise sterile body fluids, such as blood or cerebral spinal fluid, so isolation of the organisms is clear evidence of disease. Complications of severe SSSS include hypovolemia, hypothermia, and secondary infection. Standard treatment includes antistaphylococcal antibiotics, fluid and electrolyte management, and supportive care. In severe cases, patients require admission to an intensive care unit or burn unit.

CRITICAL INTERVENTIONS

- Establish that an urticarial rash is not caused by anaphylaxis.
- Establish that urticaria is not angioedema.
- Obtain clear and detailed exposure histories.
- Document MMR immunization history.
- Perform effective exposure control for pregnant patients and immunocompromised patients potentially exposed to suspected measles and rubella.

Common Pitfalls

- Extensive workups are usually not needed. Focus on a detailed history and physical examination.
- Not all urticaria is benign. Lymphoma, SLE, vasculitis, and other systemic diseases may present with urticarial.
- Failure to confirm immunization status.
- Failure to recognize that patients with suspected or diagnosed measles who exhibit mental status changes or respiratory distress are at high risk for encephalitis or pneumonia.
- The use of amoxicillin or ampicillin for pharyngitis when the illness is caused by Epstein–Barr virus can result in a morbilliform rash.

CHAPTER 282

Rashes: Vesicular, Pustular, and Scaly Lesions

Martin I. Herman, W. Ricks Hanna, Jr., and Mindy Longjohn

Skin disorders displaying vesicles, pustules, or scales may be caused by wide variety of diseases. Most commonly rashes in this category are caused by Herpes simplex, Varicella, Coxsackie, Herpes zoster, and other enteroviruses. They may also due to entities such as, eczema, atopic dermatitis (AD), seborrheic dermatitis and impetigo, among many others (see Tables 282.1 and 282.2).

TABLE 282.1
Diseases Associated with Vesicles by Pathologic Class

Infectious	Allergic, Auto-Immune	Metabolic	Deficiency Disorders
Chicken pox	Dermatitis medicamentosa	Congenital erythropoietic porphyria	Pellagra, acrodermatitis enteropathica
Coxsackie virus, hand foot and mouth disease	Dermatitis, contact	Erythropoietic protoporphyria variant	Vegetative, autonomic, endocrine disorders
Disseminated GC	ID reaction	Hematoerythrpoietic porphyria	Dishidrosis
Herpes simplex, labialis, genitalis	TEN	Developmental	Toxicologic
Herpes zoster	Pemphigus, bullous	Neonatal acne	Poison ivy/oak/sumac
		Miliaria, erythema toxicum	Caterpillar dermatitis
			Chronic mercurialism
Scabies	Pemphigus, vulgaris		
Staphylococcal/scalded skin	Dermatitis herpetiformis		
Tinea pedis, capitis, cruris, corporus	PUPP syndrome of pregnancy		
Rickettsial pox	Drug-induced photodermatitis		
Monkey pox	Linear IGA dermatosis		
Small pox			

TABLE 282.2
Eczematous Rashes

Eczematous Rash	Age Group Mostly Affected	Characteristics
Seborrhea	Infancy, adolescents, adults	Nonpruritic, erythematous to salmon-colored plaques, scaly or greasy; on scalp, face, retroauricular, intertriginous area
Psoriasis	Children, adults	Round erythematous plaques with loosely adherent silvery or grayish scales, nail pitting, (irregular and large size), extensors, genitalia and scalp
Guttate psoriasis (droplet-like)		Symmetrically distributed plaques over trunk and proximal extremities; may be associated with streptococcal infection
Scabies	Children, adults	Linear burrows, nodules to vesicles; along the web spaces between the fingers and toes, may be on scalp, hands and feet in infants
Cutaneous candidiasis	Neonates, infants	Diaper area and skin folds, papules to pustules at the margins of erythematous plaques, satellite lesions (papules with fine scales)
Nummular (discoid) eczema	Adolescents	Chronic coin-shaped (>5 cm), erythematous base with papules and vesicles, no clearing in center (central clearing seen with tinea); can be generalized, on extensor surfaces in teenagers and fingers in young females
Dyshidrotic eczema	Teenagers, adults	Palms, soles, lateral fingers, clustered vesicles (tapioca-like), pruritic, with later stage of painful fissures and erosions
Tinea	Children, adults	Scaling plaque with raised vesicular or pustular margin, central clearing
Dermatophytid reaction (id reaction)	Children, adults (reaction to fungal antigen)	Redness of skin to red papules to oval plaques; face, neck, proximal extremities, trunk
Granuloma annulare	Children, young adults	Papules and plaques, shiny, erythematous or violaceous or skin-colored, single or confluent, ring-shaped; hands, feet, elbow, knees along dorsal surface
Asteatotic eczema (eczema craquelé)	Adolescents, old age (overbathing, winter months, low humidity)	Dry, cracked skin with red fissures, extensor surfaces
Pityriasis rosea	Children (spring and autumn)	Herald patch followed by papular to plaque-like rash in the skin line distribution (Christmas tree along the back); may be inverse in African-American children, with the rash along the extremities and sparing the trunk
Allergic contact dermatitis	More likely after 3 yrs of age (delayed hypersensitivity reaction)	Papules and vesicles in linear pattern (poison oak or Rhus dermatitis); direct contact areas (e.g., nickel dermatitis)
Irritant contact dermatitis	Any age (caused by direct irritant contact)	Well-demarcated rash on face caused by contact with saliva in infants, diaper dermatitis caused by contact with ammonia in stool, juvenile plantar dermatosis caused by occlusive shoes
Wiskott–Aldrich syndrome	Male infants (X-linked recessive disorder)	Severe eczematous rash, petechiae (caused by thrombocytopenia), increased susceptibility to pyogenic infections, elevated serum IgA and reduced serum IgM
Hyper IgE syndrome (Job syndrome)	Infancy (autosomal dominant disorder)	Chronic dermatitis, recurrent staphylococcal or streptococcal skin, sinus, pulmonary infections, markedly elevated IgE (greater than 2,000 IU/mL), defective neutrophils chemotaxis, cold abscess
Phenylketonuria	Neonates	Eczematous rash, associated features of mental retardation, seizures, photosensitivity, hypopigmentation
Acrodermatitis enteropathica	Infancy (enzyme deficiency in absorbing oral zinc)	Bright red plaques, vesiculobullous rash along perianal and perioral area; associated diarrhea and failure to thrive
Hartnup disease	Infancy (autosomal recessive disorder, defect in tryptophan absorption)	Rash in light exposed area, well-marginated eczematous scaly lesions; associated with cerebellar ataxia
Pellagra	Children, adults (niacin deficiency)	Dermatitis, diarrhea, dementia, rash in areas of sun exposure or around skin friction, symmetric, erythematous
Histiocytosis X (Letterer–Siwe Disease)	Infancy	Seborrheic rash on scalp, retro-auricular and intertriginous areas (papules to plaques; yellow to reddish brown or purplish hemorrhagic appearance, vesicles)

Diagnostic accuracy can be enhanced by keeping a broad differential in mind and not limiting oneself to those rashes that are common and familiar (1). Always start with a detailed history. When did symptoms start? Where did the rash first start? Has the rash changed since first being noticed? Has it migrated since initial presentation? Are there associated signs and symptoms? Is there a history of recent exposure to infectious disease, chemicals, or plant toxins, travel, or new or recent medication use? What interventions have already been tried to treat the condition? Is anyone else affected? Are there any underlying medical conditions? Is there any prior history of similar rash? Other factors, such as age, will also help to formulate a working diagnosis.

The physical examination should focus on the characteristics of the lesions, their location and color, the appearance of the surrounding tissue, size of the lesions, their shape, and tendency to cluster or coalesce. Associated signs or symptoms including fever, lymphadenopathy, and general appearance are also helpful. Look for the presence of dermatologic signs like Koebner phenomena (appearance of lesions in areas of recent trauma), Nikolsky sign (separation of epidermis from dermis with shearing pressure), or the Aspitz sign (punctate bleeding after scale removal) (1). Laboratory testing is occasionally necessary for diagnosis by culture, polymerase chain reaction, or other indicated tests, depending on the differential diagnosis.

DISEASES WITH VESICULAR OR PUSTULAR LESIONS

Herpes Simplex

After the neonatal period, infection with herpes simplex virus (HSV) is often asymptomatic. The most common manifestation is the common cold sore, but the most common ED presentation is acute herpetic gingivostomatitis, often associated with reduced oral intake and dehydration (see Chapter 240, Oral Lesions) (2).

Clinical Presentation

HSV usually presents as discrete vesicles in tight crops or as a confluence of several vesicles in a confined area (Fig. 282.1). Typically, eruptions do not spread, though areas such as the fingers or genitalia can be seeded by autoinoculation. Corneal infection may also occur in association with lesions around the eye (Fig. 282.2). An outbreak may last 1 to 2 weeks and infected children can shed virus for a week or more, spreading HSV to playmates and household contacts. Other less common presentations of HSV infection include herpes gladiatorum and herpes rugbiaforum, which occur in wrestlers and rugby players, respectively (2).

FIGURE 282.1 Crop of vesicular lesions on a cheek.

FIGURE 282.2 Typical HSV lesions on or about the eye lid margins. (Dr. K. L. Hermann, Centers for Disease Control.)

In adolescents and adults, genital herpes (Figs. 282.3 and 282.4) is the most common presentation of HSV. It presents with vesicular or ulcerative lesions of the genitalia and surrounding tissues. In young children there are rare cases of innocently acquired primary herpes simplex infection presenting as herpetic vulvovaginitis; however, the possibility of sexual abuse must be considered in all of these cases.

HSV typing can help to indicate whether the inoculation occurred from a primary site, such as a cold sore on the lip usually associated with HSV-1, or from genital contact, which is often caused by HSV-2. However, there can be substantial overlap. Other primary and recurrent herpes infections, such as herpetic whitlow (Fig. 282.5) and herpes keratoconjunctivitis, may be seen in children. Children with AD may develop extensive herpes simplex infection on eczematized areas (eczema herpeticum).

FIGURE 282.5 HSV infection of a finger is called a herpetic whitlow. Grouped, fluid-filled, or pus-filled, blisters are typical. (From Goodheart HP. *Goodheart's Photoguide of Common Skin Disorders.* 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003.) (Copyright Dr. P. Marazzi/SPL/Science Source/Photo Researchers.)

ED Evaluation

Neonatal HSV infection can be associated with severe morbidity or even mortality and hence should not be overlooked. It can present as disseminated disease, especially with pulmonary and liver involvement, which account for 45% of cases. It may also manifest as localized central nervous system (CNS) disease (30% of cases) or as an infection localized to the skin, eyes, and mouth (SEM) (25% of cases). Neonatal HSV may occur up to the age of 4 weeks from birth and should be part of the differential diagnosis for neonates with fever. Many HSV-infected babies do not have skin lesions at presentation, as skin lesions tend to present later than disseminated disease (2).

If vesicles are seen and HSV is suspected, it can be confirmed through the use of viral cultures, fluorescent antibody staining, or enzyme immunoassay. Polymerase chain reaction (PCR) can detect HSV DNA in the CSF. Swabs should be taken from the mouth, nasopharynx, conjunctivae, and rectum. Cultures should be collected from skin vesicles, urine, blood, and CSF.

Suspected corneal infection with HSV mandates consultation with an ophthalmologist or, at a minimum, fluorescein staining of the cornea to look for dendritic keratitis (Fig. 282.6). The diagnosis can be verified by immunofluorescence, PCR, or Giemsa stain (3).

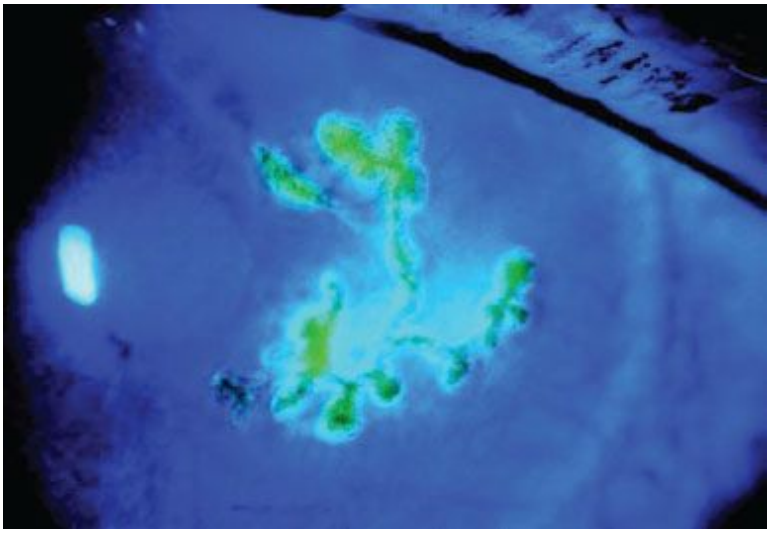

FIGURE 282.6 The hallmark of herpes simplex keratitis is the dendrite, a branching, epithelial ulceration with swollen, raised edges and terminal bulbs. (From Tasman W, Jaeger E. *The Wills Eye*

Hospital Atlas of Clinical Ophthalmology. 2nd ed. Lippincott Williams & Wilkins; 2001.)

For patients with presumed genital herpes, the diagnosis should be confirmed by culturing material from the lesions and ordering serologic testing. Other sexually transmitted diseases should also be tested, as they commonly occur together.

ED Management

Neonatal HSV can be a medical emergency; hence, neonates are usually admitted for evaluation and treatment. HSV infections after the neonatal period involving skin and mucus membranes can be treated with analgesics and, if recommended, antiviral agents.

Acyclovir, valacyclovir, famciclovir, or penciclovir may be used to treat genital herpes. Penciclovir topically, or acyclovir or valacyclovir orally, can help quell cold sores as well. HSV of the cornea or eye should be treated with topical antiviral agents; 1% trifluridine, 0.1% iododeoxyuridine, or 3% vidarabine have been shown to be effective for HSV keratitis (2). Providers should check treatment guidelines available from the CDC, the Infectious Disease Society, or the AAP Red Book for the most recent recommendations.

Varicella

Clinical Presentation

Varicella (chicken pox) is a highly infectious disease caused by the varicella-zoster virus (VZV, also known as HHV 3) (4). In the pre-vaccine era, nearly 90% of cases involved children younger than 15, with the majority of cases occurring in preschool and early school-aged children. Prior to the introduction of the VZV vaccine in 1995, varicella occurred, with an average annual incidence of approximately 150 cases per 1,000 patient years or 15 to 16 cases per 1,000 population. In the post-vaccine era, the reported incidence is down to 15.8 cases per 1,000 patient years, representing an approximately 90% reduction (5).

Signs and symptoms of varicella develop in healthy children after an average incubation period of 14 to 16 days (range, 10 to 21).

Following a 1 to 2 day prodromal state characterized by fever, headache, anorexia, cough, coryza, sore throat, and cutaneous itching, varicella skin lesions (in an unvaccinated individual) begin to appear in crops (6). The lesions begin as macules that rapidly progress to papules, then vesicles that eventually rupture and crust over. The classic early vesicle is small with circumscribed erythema, often referred to as a *dewdrop on a rose petal.* The first lesions often develop on the face and scalp and as the rash spreads, lesions of all stages (papules, vesicles, crusts) are characteristically present within a single affected area (Fig. 282.7). Shallow ulcers often occur in the mouth and may appear on other mucous membranes. Pruritus is common, and scarring may result if lesions are aggressively scratched or become superinfected.

FIGURE 282.7 Dew drop on rose petals, lesions in various stages of progression. (From Goodheart HP. *Goodheart's Photoguide of Common Skin Disorders.* 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003.)

Unvaccinated patients typically have 250 to 500 lesions in various stages, whereas vaccinated patients may have less than 50 (5). Chicken pox is contagious from 1 to 2 days before the onset of rash until all lesions are crusted over, which is typically 4 to 7 days after the onset of rash. VZV remains dormant in sensory nerve ganglia and can be reactivated later in life causing herpes zoster (i.e., shingles).

The epidemiology and clinical characteristics of varicella have changed with the implementation of the varicella vaccine program. Varicella that develops more than 42 days after vaccination (i.e., breakthrough varicella) typically is mild, with fewer than 50 skin lesions, minimal fever, and a shorter (4 to 6 days) duration of illness. The rash is predominantly maculopapular rather than vesicular in most cases (7).

Complications of varicella are rare but can be serious. The most common complications seen in children are secondary bacterial skin infections, usually caused by group A beta-hemolytic streptococcus (GABHS) or *Staphylococcus aureus.* There have been reports of chickenpox-associated invasive group GABHS infections, including necrotizing fasciitis and streptococcal toxic shock syndrome (8,9). GABHS infection should be suspected in children with varicella who develop localized skin swelling, warmth, redness, or pain. Most importantly, it should be considered in patients with fever persisting beyond the fourth day of illness or with a recurrence of fever after becoming afebrile (10). Other serious complications in children include acute cerebellar ataxia, encephalitis, encephalopathy, and post-viral transverse myelitis. Varicella pneumonia is rare in immunocompetent children but may occur in adolescent and adult patients. Deaths from varicella have diminished significantly since the VZV vaccine program was instituted dropping to only 112 in a 5-year period (10).

Patients with altered cell-mediated immunity, such as children with leukemia who are on chemotherapy, are susceptible to disseminated varicella and may have hemorrhagic lesions, pneumonitis, and encephalitis. Children with HIV can develop chronic or recurrent varicella, with new lesions appearing over the course of months. Severe varicella has also been reported in healthy children receiving intermittent courses of corticosteroids for treatment of asthma or other illnesses (2).

Differential Diagnosis

The differential diagnosis of varicella can be quite extensive and includes Herpes simplex, Herpes zoster, and rickettsial pox, as well

as zoonotic pox viruses. Other entities associated with vesicular-bullous lesions should also be included in the differential (see Tables 282.1 to 282.3). Shingles or zoster is caused by the same virus that causes chickenpox, when a previously dormant VZV infection is reactivated. The lesions look similar to those of varicella but are limited to the dermatome of the affected nerve roots. Several of the enteroviruses and parechoviruses cause vesicular skin lesions, the best known being hand–foot–mouth disease (HFMD) (Fig. 282.8). These lesions are similar to those of varicella, but their characteristic distribution sets them apart. The lesions of scabies, with associated excoriation secondary to intense itching, may appear similar to late-stage varicella lesions. Insect bites resulting in papular urticaria (e.g., from bedbugs) may also mimic early varicelliform lesions or atypical varicella. The variable manifestations of drug reactions, erythema multiforme, and syphilis should also be considered.

TABLE 282.3
Differential of Vesicular–Pustular Lesions

Varicella	Secondary syphilis
Herpes zoster	Acne
Herpes simplex	Scabies and other insect bites
Vaccinia (vaccine reaction)	Impetigo
Enterovirus	Drug rash
Molluscum contagiosum (especially HIV pts)	Erythema multiforme
Monkey pox	Contact dermatitis

FIGURE 282.8 Subtle clear vesicles on erythematous bases located on the fingers, toes, hands, feet, lips and oral mucosa.

ED Evaluation

Patients should be placed in isolation, with respiratory precautions (including a mask). Contact with caretakers who might be pregnant or immunocompromised should be avoided. A vaccine record is helpful in determining whether the case is vaccine related or atypical. Identify complications of varicella such as pneumonia, keratitis, meningoencephalitis, or secondary skin infection and initiate treatment if indicated. If corneal involvement is suspected, consultation with an ophthalmologist is strongly suggested. Classic varicella is usually easily recognized, and laboratory testing is usually not needed. When the diagnosis is in doubt, a viral culture is the recommended standard. In both varicella-zoster and herpes simplex infection, Tzanck smears prepared from vesicle scrapings may demonstrate single- or multi-nucleated giant cells with intranuclear inclusions. PCRs are very sensitive and specific for viral DNA. Direct fluorescent antibody tests are more rapid and sensitive than culture, but less sensitive than PCR testing. “Real-time” PCR tests show very high sensitivity and specificity and may in time replace direct tests or viral cultures (2).

ED Management

Children suspected of having chicken pox usually do not require more than fever control and symptomatic treatment of pruritus. Varicella may be associated with thrombocytopenia, making ibuprofen and other nonsteroidal anti-inflammatory drugs contraindicated; however, acetaminophen remains an appropriate antipyretic. Topical measures such as cool baths, calamine lotion, and colloidal oatmeal baths may help alleviate pruritus. Oral antihistamines may be helpful for severe itching; topical antihistamines, however, are less desirable because of the risks of sensitization and excessive systemic absorption through nonintact skin.

Antiviral medications have a limited window of opportunity for treatment of varicella-zoster infection. Some patients who are at risk for moderate to severe illness (age over 12 years, chronic cutaneous or pulmonary disorders, current treatment with inhaled steroids or chronic salicylates) may benefit from a prescription for oral acyclovir if it is administered within 24 hours of the onset of rash. Intravenous acyclovir is recommended for immunocompromised patients with varicella-zoster infection and should be initiated early.

If the history, examination, or laboratory testing indicates the presence of complicating factors, these should be addressed. Symptomatic dehydration requires fluids, ideally administered orally, but intravenously if the patient refuses to drink. The presence of secondary bacterial infections mandates treatment with antibiotics. In the era of methicillin-resistant staphylococcus (MRSA), treatment with antibiotics such as clindamycin, ceftriaxone, cefuroxime, linezolid, or vancomycin may be necessary, depending on the severity of the illness and local antibiotic susceptibilities. Airborne and contact precautions are recommended for patients with varicella for a minimum of 5 days after onset of the rash and for as long as vesicular lesions are present. Post-exposure prophylaxis includes either varicella-zoster-immune globulin (VariZIG) within 96 hours for high-risk susceptible persons, or varicella vaccine within 72 hours after varicella exposure for susceptible children (see the CDC guidelines or the AAP *Red Book* for current recommendations).

Most patients may be discharged home with fever control and antipruritics. Hospitalization may be needed if the patient cannot maintain hydration or requires oxygen or intravenous medications.

Herpes Zoster

Herpes zoster (shingles) is caused by a reactivation of latent VZV in sensory ganglia. Children are less commonly affected than adults, and younger patients tend to have a less painful course and little post-herpetic neuralgia (11). Risk factors for shingles include varicella acquisition in utero or prior to 18 months of age, general aging, and immunosuppression. Roughly 15% to 30% of the population will experience zoster at some point in their lives.

Clinical Presentation

The characteristic findings include grouped vesicular lesions in a dermatomal distribution (Figs. 282.9 and 282.10) accompanied by pain and tenderness along the course of the involved nerves. The most common sites are the areas supplied by the trigeminal nerve and the thoracic ganglia. Fever and local lymphadenopathy are common.

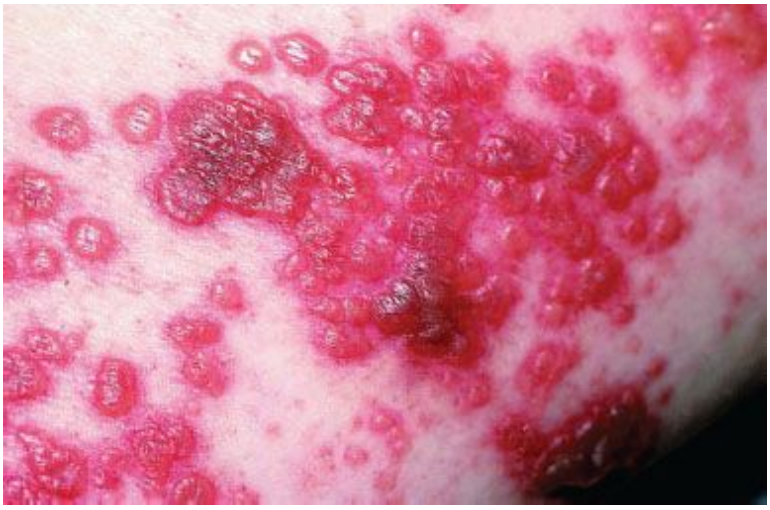

FIGURE 282.9 Discrete and confluent small vesicles with an erythematous base. (From Goodheart HP. *Goodheart's Photoguide of Common Skin Disorders.* 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003.)

FIGURE 282.10 Shingles demonstrating a right thoracic dermatomal distribution.

ED Evaluation

The history and physical should concentrate on the location and duration of the eruption, and whether symptoms are indeed dermatomal. A common history is of recent contact with a child who has chickenpox. Multi-dermatomal distribution usually represents disseminated infection, which is more common in immunocompromised individuals. If there is any suggestion of eye involvement, such as lesions on the tip of the nose or eyelids, the patient should be evaluated by an ophthalmologist.

Reactivation of VZV can also cause aseptic meningitis, cerebellar ataxia, encephalitis, or encephalopathy. Ancillary diagnostic testing such as lumbar puncture, brain CT or MRI, and or supplemental treatment may be required (11).

ED Management

Adequate analgesia, with opioids if necessary, is an important component of care (Calamine lotion does not appear to be beneficial for VZV-related pain (12)). Famciclovir, valacyclovir, or acyclovir

may be helpful. Acyclovir 20 mg/kg (max 800 mg/dose) can decrease healing time and decrease associated pain (11) (note: Famciclovir and valacyclovir are licensed for use only in adults) (1). Most patients with shingles can be sent home with analgesics and antihistamines such as diphenhydramine to reduce itching.

Enteroviruses

Clinical Presentation

HFMD (see Fig. 282.8) is a distinctive clinical syndrome that is usually caused by Coxsackie A16 or enterovirus 71. Sporadic cases have been associated with Coxsackievirus A4-A7, A9,10, B1–3, and B5 (6).

A 2- to 4-day prodromal stage of fever, anorexia, sore throat, and abdominal pain occurs prior to the appearance of the rash. The lesions are typically 2 to 8 mm, large, oval, gray blisters noted on the sides of the fingers as well as the palms and soles, and usually with an erythematous halo. Apthous ulcers may be seen on the palate, tongue, and buccal mucosa. The rash generally lasts 5 to 10 days (4). Complications of HFMD include aseptic meningitis, encephalitis, paralysis, and death. Outbreaks of HFMD associated with neurologic complications and death have been linked with enterovirus 71 (13).

ED Evaluation

The diagnosis of an enteroviral infection is usually based on the clinical findings. Confirmatory testing may be desired, however, and can be done for many of the agents. Cell culture is the standard method; specimens obtained from the rectum, stool, or throat have the highest yield, but the virus may be recovered from CSF, blood, and urine as well. PCR assays are available for enteroviruses and are more rapid and sensitive than cell culture.

ED Management

Fever control and hydration are particularly important issues and are the mainstays of management. Patients should be adequately hydrated, and their ability to drink, especially in patients with mucous membrane involvement, should be carefully assessed. If the patient is unable or unwilling to drink, intravenous fluids should be

given. Analgesics should be provided as necessary, but the use of topical anesthetics like viscous lidocaine in younger patients should be discouraged, as aspiration and toxicity may result. Application of aluminum hydroxide and magnesium hydroxide or sucralfate may be helpful in ameliorating stomatitis-related pain (14), though controlled studies have not shown a clear benefit (15).

Most patients with HFMD, herpangina, or other enteroviral infections may be discharged home if they can demonstrate their ability to take adequate fluid. Fever can be managed with antipyretics at home. Spread of the enteroviruses should be contained by meticulous hand washing, disinfection of surfaces, and avoiding the popping of any vesicles. Patients with CNS infection and an altered level of consciousness or muscle weakness should be hospitalized. Cardiac monitoring in the hospital is appropriate for patients with myocarditis or pericarditis caused by enteroviral infection. Vaccines are being researched as are chemotherapeutic agents, but thus far none has been approved for use in the United States.

Impetigo

Impetigo is an infection of the superficial epidermis by *Staphylococcus aureus* and/or *Streptococcus pyogenes* that presents with multiple vesicular lesions on an erythematous base, which usually crust over. The infection is highly contagious; humidity, crowding, and poor hygiene all contribute to its spread. Children ages 2 to 5 years are most often affected (16,17). It is most common on exposed areas of the body, including the face, extremities, and scalp. Minor skin abrasions, minor trauma, burns, insect bites, diabetes mellitus, varicella infection, HIV infection, and pre-existing skin disease are all predisposing risk factors.

Clinical Presentation

There are two types of impetigo: nonbullous and bullous (Figs. 282.11 and 282.12). Nonbullous impetigo is more common and is usually secondary to a mixed infection with *Staph. aureus* and *Strep. pyogenes*. It begins as a single red macule or papule that becomes

vesicular. The vesicle ruptures, forming an erosion, and the contents of the vesicle dry, leading to the classic thick honey-colored crust. Nonbullous impetigo is spread to adjacent areas by autoinoculation, especially in areas subject to environmental trauma, such as the face and extremities. This leads to clustering of the vesicles before the breakdown and crusting of the lesions. Pain and pruritus are not common but may occur. Regional lymphadenopathy may be an isolated finding.

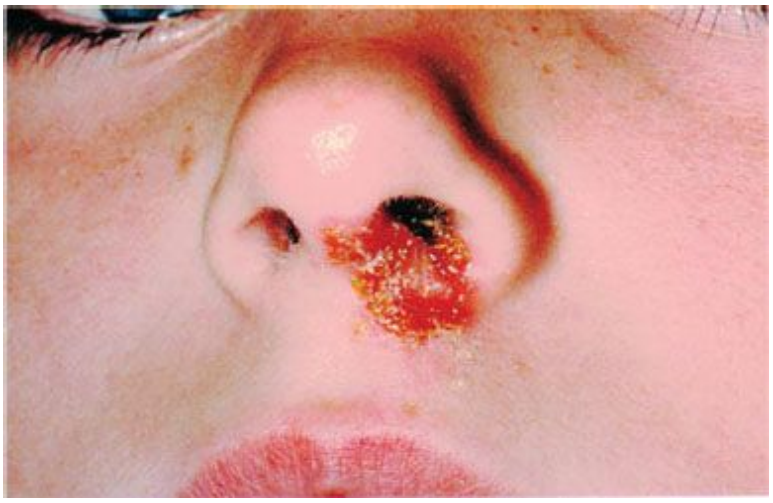

FIGURE 282.11 Typical honey-colored crusts. (From Smeltzer SC, Bare BG. *Textbook of Medical-Surgical Nursing.* 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2000.)

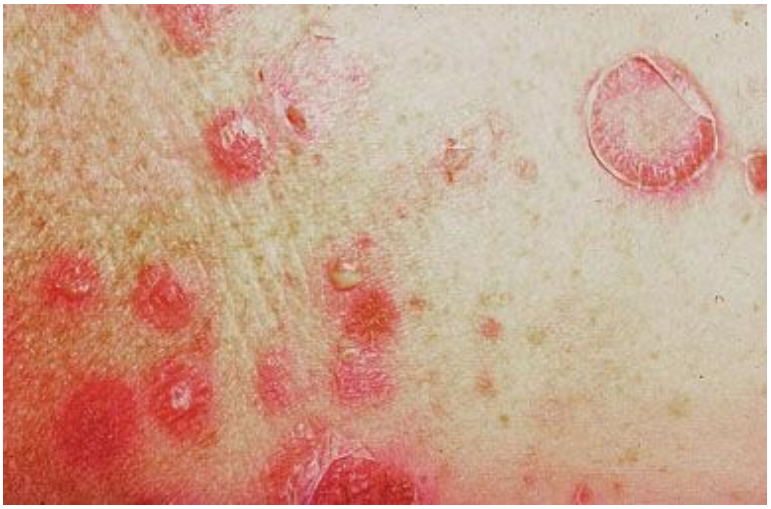

FIGURE 282.12 Blebs, bullae, and coin-shaped lesions that remain after the bleb is removed.

Common or impetiginous impetigo (also called secondary impetigo) is a subtype of nonbullous impetigo (16). This is a complication of systemic diseases such as diabetes mellitus and acquired immunodeficiency syndrome or may be secondary to processes that cause a break in the skin, such as insect bites or herpes simplex. Secondary impetigo proceeds similarly to nonbullous impetigo.

Bullous impetigo is less common and is usually seen in newborns and infants but can occur in any age group. The bullous form is caused by toxin-producing *Staph. aureus* and is considered a localized form of staphylococcal scalded skin syndrome. Bullous impetigo begins as vesicles that progress to enlarging, flaccid bullae with sharp margins and no surrounding erythema. The bullae are filled with yellow fluid that crusts over after rupture. A collarette of scale surrounding the blister roof at the periphery of ruptured lesions is pathognomonic (Fig. 282.13) (16). Bullous impetigo is common in moist body areas, including the diaper area, axilla, and neck folds. There are usually no systemic symptoms, and regional lymphadenopathy is rare. As compared to the nonbullous form, cases of bullous impetigo are less contagious and tend to be sporadic.

FIGURE 282.13 Collarette of scale surrounding the blister roof at the periphery of ruptured lesions is pathognomonic. (From Goodheart HP. *Goodheart's Photoguide of Common Skin Disorders.* 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003.)

Differential Diagnosis

The differential diagnosis of nonbullous impetigo includes AD, candidiasis, contact dermatitis, dermatophytosis, discoid lupus erythematosus, herpes simplex, insect bites, pemphigus, scabies, Sweet syndrome, and varicella infection. The presence of the honey-colored crust and the distribution of the lesions are important differentiating factors in impetigo.

Varicella infection is unique in that the vesicles appear in crops and that there are usually lesions of different ages present concurrently. Sweet syndrome is a rare skin condition presenting with fever, arthritis, and the sudden appearance of bluish-red tender papules located asymmetrically on the arms, legs, and face.

Bullous impetigo can mimic cigarette or thermal burns and can be mistaken for child abuse (16). It is also important to differentiate bullous impetigo from Stevens–Johnson syndrome and toxic epidermal necrolysis (TEN). These diagnoses represent a continuum and are potentially life threatening. Stevens–Johnson is a blistering process that by definition involves mucosal surfaces, usually the mouth and eyes, among others. TEN is the continuation of the blistering of Stevens–Johnson with detachment of the epidermis.

ED Evaluation

The diagnosis of impetigo is usually made on the basis of history and clinical presentation. If the diagnosis is uncertain, the organism(s) can be identified by Gram stain and culture of the lesions or the associated fluid. The lesions should be de-crusted aseptically to obtain the exudative material beneath for the appropriate studies.

ED Management

If left untreated, most cases of impetigo are self-limited with no residual scarring (16,17). The main goals of therapy are relief of discomfort, prevention of autoinoculation, limiting of spread of the

disease, and improved cosmetic appearance. Topical antibiotic therapy with mupirocin has the advantage of being applied only where needed, minimizing potential side effects. Side effects of topical antibiotics are uncommon and are usually mild if present, with skin sensitization occurring in susceptible individuals.

Oral antibiotic therapy may be needed for patients who cannot tolerate topical antibiotic therapy or who have extensive or systemic disease. Oral antibiotics are typically prescribed for 10 days and should have antistaphylococcal activity. Common oral antibiotic choices include amoxicillin/clavulanate and cephalosporins, with clindamycin and trimethoprim–sulfamethoxazole used for suspected MRSA. Combining topical and oral antibiotics is not necessary.

Approximately 1% to 5% of patients will develop acute post-streptococcal glomerulonephritis as a serious complication of nonbullous impetigo (16). Antibiotic treatment has not been found to decrease the risk of glomerulonephritis. Other more rare complications include sepsis, osteomyelitis, arthritis, endocarditis, pneumonia, cellulites, toxic shock syndrome, and staphylococcal scalded-skin syndrome. Rheumatic fever has not been associated with impetigo.

Most patients with impetigo can be discharged from the ED with topical or oral antibiotic therapy. In cases of severe infection or concerns for Stevens–Johnson syndrome or aggressive MRSA, inpatient therapy may be necessary. Follow-up should be arranged to guarantee complete and complication-free resolution.

Eczema and AD

AD is the most common chronic inflammatory skin condition in the pediatric age group (18,19). Its prevalence is 10% to 15% among children in the United States and Europe, and the incidence is noted to be increasing worldwide (20,21). AD is a chronic relapsing dermatitis that is relentlessly pruritic and often progresses to eczematous patches, with crusting and fissuring. AD affects the patient's quality of life because of intractable pruritus, loss of sleep, decreased appetite, and mood changes. The families of patients with

AD are also adversely affected through parental sleep disturbance, anxiety, depression, and the impact on the care of siblings (18,20).

AD is considered an allergic condition. Allergic disorders in children are likely to develop in genetically predisposed children after exposure to environmental triggers. The *atopic triad* (21) refers to the presence of AD, allergic rhinitis, and asthma. AD can be a lifelong condition; most cases present between the ages of 2 and 5 years. Some evidence suggests that AD may be more common in Black and Asian children (18).

Clinical Presentation

The presentation of AD is similar to most inflammatory skin conditions: Pruritus, erythema, dry skin, scaling, and eventually lichenification. Lesions may be acute, subacute, or chronic, and all stages may be present at the same time. The initial symptom is usually intense pruritus, which eventually leads to micro-trauma in the epidermis and the formation of erythematous papules with dry skin and a light scale. As AD progresses from this mild form, intense erythema and small vesicles form. Chronic changes include lichenification, especially at the skin lines and eventual fissuring (Fig. 282.14).

FIGURE 282.14 Lichenification, excoriation, hyperpigmentation of antecubital folds.

In infants, AD is typically seen on the face, scalp, trunk, and the extensor surfaces of the extremities. The perioral and periorbital areas tend to be spared. As patients grow older, the common areas are the flexor surfaces of the extremities, face, neck, wrist, and ankles. In addition to the rash, almost all patients have xerosis, or dry skin, that is exacerbated by dry climates and winter weather. Patients may also exhibit nonpigmented hyperkeratotic papules (keratosis pilaris), which form around hair follicles. Keratosis pilaris is most often found on the extensor surfaces of the upper arms, the buttocks, and the anterolateral thighs.

With repeated excoriation, the rash associated with AD can become secondarily infected, most often with *Staph. aureus* and *Strep. pyogenes* (21). Because the normal skin barrier is compromised, AD makes the patient more susceptible to cutaneous infections. Herpes simplex is among these infections; widespread herpes infection complicating AD is known as eczema herpeticum (19).

Differential Diagnosis

The differential diagnosis of AD includes other papulosquamous conditions including contact or irritant dermatitis, lichen simplex chronicus, pityriasis rosea, and psoriasis. The rash associated with allergic dermatitis is usually found on exposed areas and can also be acute, subacute, or chronic, depending on the length of the exposure. Common causes include poison ivy, nickel, rubber, latex, soaps, detergents, and cosmetics. The exposure history and the resolution of the rash with removal of the offending agent are typical clues to the diagnosis. The herald patch associated with pityriasis rosea may be confused with AD (19). Pityriasis rosea is usually not pruritic, and the typical distribution of the rash helps to differentiate it from AD. The rash associated with psoriasis is an erythematous plaque with an adherent silvery scale, giving the area a greasy appearance (19). Psoriasis is usually located on the extensor surfaces, whereas AD typically involves the flexor surfaces.

ED Evaluation

AD is usually diagnosed by history and physical examination. The most striking feature is the pruritus, which is almost universally

present. Other associated features are a history of atopy, family history of atopy, the relapsing nature of the dermatitis, and the typical appearance and distribution of the skin findings.

ED Management

The mainstays of treatment are hydration of the skin, avoidance of irritants, and the application of topical anti-inflammatory agents (21). AD is a chronic condition, and although treatment is often begun in the ED, long-term care should be coordinated through the patient's primary care provider or dermatologist. Hydration of the skin is begun with the use of lotions and creams as emollients, applied at least three to four times a day and especially after bathing. Patients should be instructed to decrease the frequency and duration of bathing since prolonged bathing may worsen the condition. Any identified skin irritants such as environmental or food allergens should be avoided; others, like winter weather or low humidity, may be difficult to avoid.

Topical corticosteroids (TCSs) have historically been the most common first-line anti-inflammatory treatment for AD and its flares (18,21). TCSs are effective in treating the acute manifestations of AD, but prolonged and unmonitored use should be avoided because of their local and systemic side effects. These side effects include the local effect of skin atrophy and systemic suppression of the hypothalamic-pituitary-adrenal axis. Young children, with their large skin surface area–body mass ratio, are at increased risk of systemic side effects owing to cutaneous absorption.

Superinfection of AD requires treatment with antibiotics effective against *Staph. aureus* and *Strep. pyogenes* along with routine skin care. Eczema herpeticum requires acyclovir and occasionally hospitalization for its control.

It is important to remember AD is a chronic relapsing condition that affects not only the patient but the entire family unit. When treating AD, it is important to take the time to discuss the importance of skin care and the various treatment options. Close follow-up is essential for children using TCSs or immunomodulators.

Pityriasis Rosea

Pityriasis rosea (PR) is a self-limited papulosquamous eruption that is common in children and young adults (22). The etiology of PR remains unclear, but there are features that suggest a role for human herpesvirus 7 (19,22,23). Cases are known to cluster within populations and are typical in the late fall and winter, with a peak in early spring. PR most commonly affects adolescents, especially between 10 and 35 years, and there is a slight female predominance.

Clinical Presentation

Patients with PR typically present after a viral prodrome (i.e., an upper respiratory tract infection, fever, malaise, arthralgias, and headache). The herald patch presents in most patients and precedes the rash. It is a 2- to 10-cm, oval-to-round plaque that is salmon colored and surrounded by a dark red rim. The center is clear and is separated from the rim by a scaly collar or "collarette." The secondary rash occurs days to weeks after the herald patch and is characterized by 5- to 10-mm, oval, and salmon-colored lesions, with the same scaly "collarette." It is found on the chest, back, abdomen, and extremities along the lines of skin tension or Langer lines; it commonly takes on a "Christmas tree" pattern on the back. Pruritus in noted in only 25% of patients (23) (Fig. 282.15). The rash usually lasts from 2 to 6 weeks but can persist for as long as 3 months.

FIGURE 282.15 Typical Christmas tree distribution with a herald patch on the right forearm. (From Goodheart HP. *Goodheart's Photoguide of Common Skin Disorders.* 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003.)

Differential Diagnosis and ED Evaluation

PR is usually diagnosed on the basis of history and the appearance and distribution of the lesions. The most important disease in the differential diagnosis is secondary syphilis. The rash associated with secondary syphilis can mimic PR, but in secondary syphilis, the palms and soles are often affected, whereas they are spared in PR. If a patient is sexually active or the diagnosis is in question, serologic testing for syphilis should be considered.

Other conditions in the differential diagnosis include nummular eczema, especially when only the herald patch is present. Other entities to be considered include tinea, guttate psoriasis, lichen planus, pityriasis lichenoides, and Kaposi sarcoma. Rarely, drug reactions have been confused with PR; some authors have searched for a causal link, but none have been found.

For pruritus, antihistamines, oatmeal soaks, and occasionally topical steroids are recommended. For severe cases of pruritus, systemic steroids may be useful.

ED Management

The patient and family should be reassured that the disease is not contagious, is self-limited, and can be expected to resolve within several weeks. Patients should be encouraged to see their physician if the rash lasts longer than 3 months. Black patients can exhibit hypopigmentation following the resolution of the rash.

CRITICAL INTERVENTIONS

- Treatment with acyclovir should be initiated in neonates who are febrile, irritable, displaying lethargy or have physical signs of HSV infections.
- Patients should receive adequate pain control.

- An eye examination should be performed in patients with disseminated disease.
- Test for syphilis in patients who present with a rash resembling pityriasis rosea.

Common Pitfalls

- Mistaking hand–foot–mouth for varicella.
- Recommending topical diphenhydramine, especially if in addition to recommending oral diphenhydramine to control itching.
- Failing to recognize that lesions on the nose may signal involvement of the cornea.
- Failure to recognize that bullous impetigo can mimic cigarette or thermal burns and can be mistaken for child abuse.
- Failure to recognize systemic HSV and to consider CNS HSV in an infant.
- Failure to realize that enteroviral infections can be associated with serious complications such as a polio-like illness, seizures, or death.
- Failure to determine the patient's or parents' ability to maintain hydration.
- Failure to recognize that high-potency steroids should not be used routinely in the perineal area.

CHAPTER 283 Common Pediatric Infestations

Jesse Walck and Martin I. Herman

Infestations refer to a state of being lived in or on as a parasite. Although infestations occur commonly they are not a cause of significant morbidity but, because of the symptoms they can produce and the near hysteria they can invoke, they are often seen in the emergency department. The following sections address some of the more common infestations.

CUTANEOUS LARVA MIGRANS

CLINICAL PRESENTATION

Cutaneous larva migrans (CLM), or creeping eruption, refers to a hookworm infection that produces a characteristic intensely pruritic serpiginous rash (Fig. 283.1) (1). The usual cause is the larvae of cat and dog hookworms found in warm climates near beach areas. CLM is a disease of children, gardeners, utility workers, sunbathers, or anyone who comes in contact with sand or soil contaminated by cat or dog feces (2,3).

FIGURE 283.1 Cutaneous visceral larva migrans. (From Farr WE, Wood MJ, Innes JA, et al. *Infectious Diseases Text and Color Atlas.* 2nd ed. New York, NY: Gower Medical Publishing; 1992.)

The larvae gain access to the human skin most commonly in the lower extremities and form a pruritic reddish papule at the site of entry. If exposed to heavily contaminated soil several papules may develop. The larva migrates within the dermis of the skin advancing several millimeters a day until they eventually die within 1 to 2 weeks. Rarely the larva can disseminate hematogenously to the lungs producing patchy infiltrates and blood eosinophilia producing a condition referred to as Loeffler syndrome (4).

Patients usually present with an intensely pruritic characteristic serpiginous erythematous rash about 2 to 3 mm in diameter. The rash is usually raised and typically occurs on the lower extremities. Some lesions may appear fluid filled or crusted and have associated nodules and blisters (4). Lesions can become secondarily infected.

DIFFERENTIAL DIAGNOSIS

CLM may be mistaken for the rash seen with tinea pedis, herpes simplex, contact dermatitis, scabies, cutaneous leishmaniasis, and myiasis (botfly skin infestation) (4).

ED EVALUATION

The diagnosis is made clinically. Biopsies or laboratory testing is not indicated.

CRITICAL INTERVENTIONS

- The infestation is self-limited after several weeks to months. Treatment is indicated to relieve symptoms and to prevent secondary infection. Ivermectin 200 μg/kg PO QD for 1 to 2 days or Albendazole 400 mg PO QD for 3 days is effective (5). Symptoms typically disappear within 1 week of treatment often before the rash resolves. Topical preparations of albendazole or thiobendazole are effective but difficult to obtain. Loeffler syndrome is treated orally at the same doses mentioned previously (4).
- Suspected secondary infections can be treated with appropriate antibiotics.

DISPOSITION

Patients can be discharged to initiate treatment at home.

Common Pitfalls

- Failure to recognize the infestation
- Attempting to extricate the worm by dissection
- Treating with topical agents

SCABIES

CLINICAL PRESENTATION

Scabies is an infestation of the skin caused by the mite *Sarcoptes scabiei* that produces a pruritic skin rash with a characteristic distribution (6).

The female mite burrows in the upper dermis of the skin creating small linear burrows. Sensitization to the mite and its eggs and feces are responsible for the pruritic reaction (6).

The infestation is contagious and obtained from human contacts or dogs. The incubation period for persons without prior exposure is 2 to 6 weeks, but in a reinfestation, symptoms may appear in as early as a few days. Norwegian or crusted scabies occurs most commonly in immunocompromised patients, is characterized by crusted or warty lesions with minimal pruritus but with high concentrations of highly contagious mites (7).

Patients usually present with an intensely pruritic erythematous rash often with characteristic burrows. However the rash is variable and can also present with papules, pustules, or nodules and burrows may not be visible due to excoriation or secondary infection. Adults often have lesions in the fingers (Fig. 283.2), web spaces and flexor surfaces of the wrists, axilla, and genital areas. Infants and young children most commonly have lesions on the face, head, neck, scalp, palms, and soles (Fig. 283.3) and the lesions are often more inflammatory than in adults (8).

FIGURE 283.2 Scabies—web spaces. (From Fleisher GR, Ludwig S, Baskin MN. *Atlas of Pediatric Emergency Medicine.* Philadelphia, PA: Lippincott Williams & Wilkins; 2004.)

FIGURE 283.3 Scabies—infants. (From Fleisher GR, Ludwig S, Baskin MN. *Atlas of Pediatric Emergency Medicine.* Philadelphia, PA: Lippincott Williams & Wilkins; 2004.)

Crusted scabies can present with crusted or warty lesions with minimal pruritus.

DIFFERENTIAL DIAGNOSIS

When considering scabies as the diagnosis, one must also include atopic dermatitis, seborrheic dermatitis, contact dermatitis, impetigo, syphilis, drug reaction, pityriasis rosea, histiocytosis X in the differential as they may appear very similar.

ED EVALUATION

The diagnosis is made or suspected based on the clinical presentation. A history of household contacts with similar symptoms makes scabies more likely. Skin scrapings can confirm the diagnosis by direct visualization of the mites by light microscopy and can be done by gently scraping a burrow with a scalpel and mineral oil and transferring to a slide.

CRITICAL INTERVENTIONS

- Permethrin cream 5% is the initial treatment for infants, young children, and pregnant or nursing women. The cream should be applied to the entire body including the head and left on for 8 to 14 hours before bathing. A second application may be needed 1 week later. Oral ivermectin given as a single dose at 200 μg/kg has been shown to be effective for treatment of scabies. It is not recommended in children under 15 kg or in pregnant or lactating women.
- Treatment of crusted scabies may require more aggressive treatment with daily topical permethrin 5% for 7 days in addition to oral ivermectin 200 μg/kg/dose on days 1, 2, 8, 9, and 15 (6,9,10).
- Pruritus may persist for days after successful treatment due to the inflammatory response to the dead mites and can be managed with antihistamines. Secondary infections if present should be treated with appropriate antibiotics.

DISPOSITION

Patients can be discharged to initiate treatment at home. Bedding and clothes should be washed in hot water or bagged for several days since the mites can only survive a few days away from the human host. Family members and close contacts should be treated at the same time. Affected individuals may return to work or school after treatment (8).

Common Pitfalls

- Failure to recognize or suspect the infestation especially in infants.
- Failure to apply the topical treatments as directed.
- Failure to recognize crusted scabies in immunocompromised patients.

PINWORMS (ENTEROBIUS VERMICULARIS)

CLINICAL PRESENTATION

Pinworms are the most common helminthic infection in the United States with prevalence estimates of up to 40 million people affected (11,12). Pinworm infections occur most frequently in preschool and school-aged children, infestations are uncommon under the age of 2 years. Infestation also occur in clusters within families and in institutionalized individuals. The eggs are transmitted via the fecal–oral route or by contamination of the hands. Sharing toys, bedding, clothing, toilet seats, and baths may promote spreading of the infection (13).

Once the eggs are ingested they hatch in the duodenum, mature and migrate to the cecum. The female pinworm migrates to the perineum at night and lays up to 10,000 eggs. Once the eggs are laid on the perineum the patient can auto infest or spread the infection to others. Scratching may collect eggs under the fingernails and lead to autoinfestation or transmission to others. The infestation usually lasts 4 to 6 weeks in the absence of autoinfestation (14).

Most infestations are asymptomatic. However patients often present to the ED with nocturnal pruritus ani. Prepubertal females may also present with pruritus vulvae and in some cases vulvovaginitis. Scratching of the rectum and vagina can lead to secondary bacterial infections. Occasionally worm burdens may be so high as to cause abdominal pain, nausea, or vomiting (13).

DIFFERENTIAL DIAGNOSIS

Any condition that leads to excoriation from scratching may be mistaken for pinworms. For example, poor hygiene, nonspecific vaginitis, UTI, sexual abuse, and streptococcal perianal infection may present with perianal abrasions, and excoriations similar to this seen with pinworm infestation.

ED EVALUATION

Diagnosis can be made by the direct visualization of the thread-like worms in the perineal region and are usually best seen at night about 2 to 3 hours after the patient has fallen asleep (14). Clear tape can be used to touch the perineal area in the morning to collect any eggs

and worms that may be present. The tape can then be viewed under a low power microscope to confirm the diagnosis (Fig. 283.4).

FIGURE 283.4 Pinworm eggs with clear tape. (From Koneman EW, Allen SD, Handa WM, et al. *Color Atlas and Textbook of Diagnostic Microbiology*. 5th ed. Philadelphia, PA: Lippincott; 1997. Fig. 20.3G.)

CRITICAL INTERVENTIONS

Pinworm infestation can be treated with albendazole 400 mg or pyrantel pamoate 11 mg/kg up to 1 gm (OTC). Both are given as a single dose and are repeated in 2 weeks with a cure rate greater than 90% (15). Oral antihistamines can be used to control pruritus.

DISPOSITION

Patients can be discharged to initiate treatment at home. Good hand and fingernail hygiene, cleaning of all bedding and showering in the morning should help prevent reinfestation. Household contacts should be treated as well.

Common Pitfalls

- Failure to treat household contacts.
- Failure to recognize pinworms as a possible cause of vaginitis in prepubertal females.

HEAD LICE

CLINICAL PRESENTATION

Pediculosis capitis (head lice) is an infestation caused by the head louse *Pediculus humanus capitis* and commonly affects children and adults. Head lice are not indicative of personal hygiene and can affect all socioeconomic classes. Head lice are less common in African Americans possibly due to the suspected ability of the louse to preferentially grasp certain shapes or widths of hair. Lice live close to the scalp and the female lays about 10 eggs/day usually within 4 cm of the scalp. The eggs or nits are firmly attached to the hair shafts and hatch within about 10 to 14 days (Fig. 283.5). As the louse sucks blood from the scalp an immunologic response occurs on the scalp which is responsible for the pruritis (6,16).

FIGURE 283.5 Head lice (nits). (Courtesy of Hans B. Kersten, MD.)

Lice have not been shown to carry communicable disease. Lice can be spread by direct contact and by shared clothing, combs, brushes, or bedding. Lice do not jump.

CLINICAL PRESENTATION

The patient with head lice may present with pruritus to the scalp, behind the ears or at the nape of the neck. Cervical and occipital lymphadenopathy may be present (16). The lice and nits are visible on inspection. Head lice may be asymptomatic and be found as an incidental finding. Secondary infections may be present.

DIFFERENTIAL DIAGNOSIS

Seborrheic dermatitis, tinea capitis, and folliculitis should be considered in making the diagnosis. Other types of lice infestations may occur such as body lice (*Pediculus humanus humanus*) and crab lice (*Pthirus pubis*), these may be differentiated by their morphology (see Fig. 283.6).

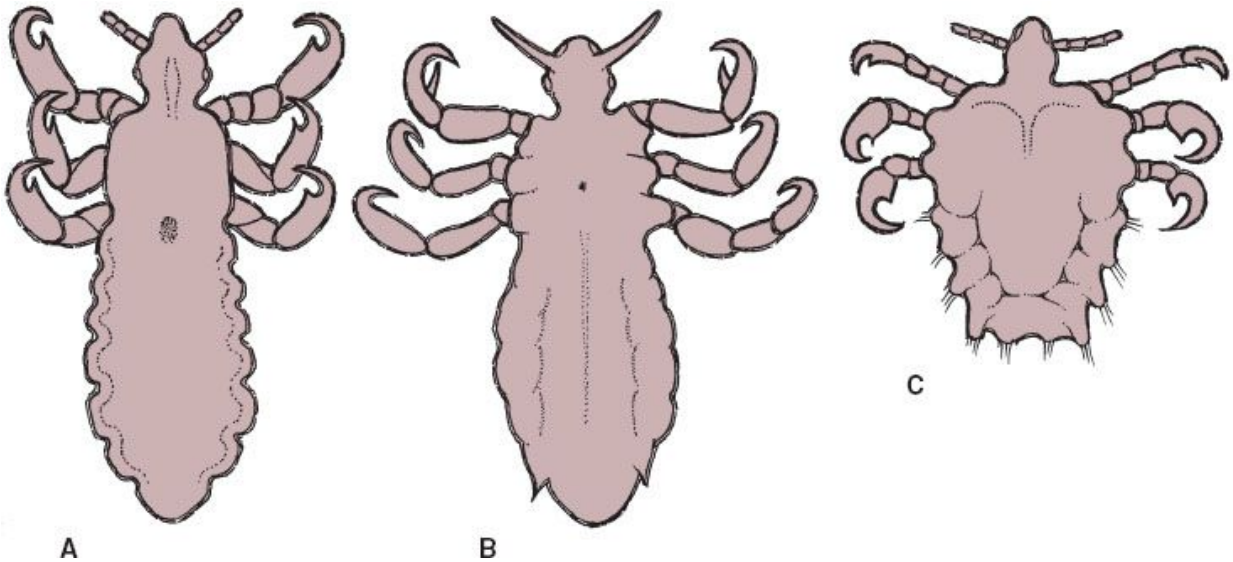

FIGURE 283.6 Common lice of humans; **(A)** head louse (*Pediculus humanus capitis*), **(B)** body louse (*Pediculus humanus humanus*), **(C)** public louse (*Pthirus pubis*). (From Stedman's Medical Dictionary. 28th ed. Philadelphia, PA: Lippincott Williams & Wilkins.)

ED EVALUATION

Diagnosis is made by visualization of nits and live lice. Presence of nits alone does not diagnose an active infestation (8). Lice fluoresce a pale blue under the woods lamp (6).

CRITICAL INTERVENTIONS

- Several treatments are effective and available. See Tables 283.1 and 283.2 (5,6,8,16).
- The effectiveness of head lice treatment by suffocation with occlusive agents such as mayonnaise, peanut butter, petroleum jelly, oil, or butter has not been adequately studied. Shaving hair has not been studied as a treatment to eradicate head lice.
- Oral antihistamines can be used for the pruritus.
- Head lice and eggs are killed by exposure to temperatures achieved by hot water washers and hot air dryers.

TABLE 283.1
Topical Treatments

Topical	Age	Dose	Consideration
Permethrin 1% lotion (Nix)	>2 mos	Apply for 10 min	Kills live lice only Reapply in 1 wk if live lice seen
Pyrethrins (RID, Pronto, TripleX) OTC	>2 yrs	Apply for 10 min	Kills live lice only Reapply in 1 wk
Malathion	>6 yrs	Apply for 8–12 hrs	Kills lice and partially ovicidal Reapply in 1 wk if live lice seen Flammable
Benzyl alcohol 5% lotion	>6 mos	Apply for 10 min	Kills lice and partially ovicidal Reapply in 9 d if live lice seen
Ivermectin 0.5% lotion	>6 mos	Apply for 10 min	Single application
Spinosad suspension 0.9%	>4 yrs	Apply for 10 min	Contains benzyl alcohol and spinosad Reapply in 7 d if live lice seen
Lindane 1% shampoo	No longer recommended for infants or children	Potentially neurotoxic if swallowed	Kills lice and ovicidal

TABLE 283.2
Oral Treatment for Pediculosis

Oral	Age	Dose	Considerations
Ivermectin 200–400 µg/kg	>15 kg	One-time dose	Usually reserved for infestations resistant to topical therapy May need second dose in 1 wk
Trimethoprim-sulfamethoxazole 10 mg/kg/d TMP-divided BID	>2 mos	10-d course	Used in combination with topical permethrin for resistant infestations

DISPOSITION

Patients can be discharged and treatment initiated at home. Surviving nits and lice are killed by exposure for greater than 5 minutes to temperatures of greater than 53.5°C, therefore clothing worn by the infested person over the 2 to 3 days before treatment can be washed. Extensive housecleaning is not necessary since lice cannot survive for more than 1 to 2 days if unable to feed (5,17).

Common Pitfalls

- Assumption that presence of lice is a sign of poor hygiene.
- Overestimation of lice's ability to be transferred from person to person.
- Failure to repeat treatment if needed.

CHAPTER 284

Immunizations

Sandra L. Grossman and Marla J. Friedman

Immunizations have been instrumental in reducing the incidence, morbidity, and mortality of preventable diseases throughout the world. Childhood immunization has been a cornerstone of pediatric health care since the first American Academy of Pediatrics (AAP) policy statement on immunization practices was released in 1977. Despite recommendations of universal immunization, only 77% of children in the United States aged 19 to 35 months received their routine immunization series in 2011 (1,2). Adolescent vaccination coverage, however, has increased, with Tdap coverage reaching the *Healthy People 2020* target of 80% (3). Most concerning are children living below the poverty level, whose immunization rates are reported to be as low as 64% (4). Although most routine immunizations are administered in a primary health care setting, many view an emergency department (ED) visit by an underimmunized child as an opportunity to vaccinate.

CLINICAL PRESENTATION

Recent Recommendations and Controversies

The schedule in Table 284.1 represents the most recent recommendations from the AAP, the Centers for Disease Control and Prevention (CDC), and the American Academy of Family Physicians (AAFP) for routine childhood immunizations. This schedule is reviewed and updated annually to include new vaccines and revised recommendations. Combination vaccines and their approved uses are presented in Table 284.2. Interim information on vaccines,

schedules, and adverse events can be found on the AAP website (www.aap.org), the AAFP website (www.aafp.org), and the CDC website (http://www.cdc.gov/vaccines). The national immunization hotline is available to answer immunization-related questions from both health care personnel and the public (1–800–232–4636).

TABLE 284.1
Childhood Immunization Schedule—United States, 2013

Birth	1 mo	2 mos	4 mos	6 mos	12 mos	15 mos	18 mos	24 mos	4–6 yrs	11–12 yrs	15–18 yrs
Hepatitis B	HepB 1[a]										
		HepB 2				HepB 3			catch-up series		
DTaP		DTaP	DTaP	DTaP		DTaP			DTaP	Tdap	catch-up series
Hib		Hib	Hib	Hib[b]		Hib					
Polio		IPV	IPV			IPV			IPV	catch-up series	
MMR						MMR			MMR	catch-up series	
Varicella					Varicella				catch-up series		
Pneumococcal (PCV13)		PCV	PCV	PCV		PCV			high-risk groups[c]		
Influenza					Influenza (Annually)						
Rotavirus		Rota	Rota	Rota							
Hepatitis A	Hep A (2 doses)						high-risk groups[d]				
Meningococcal	high-risk conditions					MCV4					
HPV	HPV								catch-up series		

Children 9 mos–10 yrs of age with anatomic/functional asplenia, terminal complement deficiencies, travel to or residence in areas of epidemic meningococcal disease.
[a]If mother is Hepatitis B surface antigen negative.
[b]Not required if vaccine containing PRP-OMP (Comvax, PedvaxHIB) given at 2 and 4 mos.
[c]High-risk groups: Sickle cell disease, HIV, asplenia, diabetes, heart/pulmonary disease.
[d]High-risk groups: Chronic liver disease, clotting disorders, travel to developing countries, illicit drug use, homosexual adolescent males.
DTaP: Diphtheria, Tetanus, acellular Pertussis; Tdap: Tetanus and diphtheria toxoids, acellular pertussis; Hib: *Haemophilus influenzae type b;* MMR: Measles, Mumps, Rubella; HPV: Human Papillomavirus.

Combination Vaccines

	Approved Use	Notes
Pediarix (DTaP, IPV, hepatitis B)	Ages 6 wk–6 yr	Only for three-dose primary series Do not use for booster doses Given at 2, 4, 6 mos
MMRV (ProQuad) (measles, mumps, rubella, varicella)	12 mo–12 yr	Two doses ≥3 mo apart
Comvax (Hib, hepatitis B)	6 wk–71 mo born to HbsAg mothers	Three doses; given at 2, 4, and 12–15 mo
Kinrix (DTaP-IPV)	4–6 yr	Booster for fifth dose of DTaP, fourth dose of IPV
Twinrix (hepatitis A, hepatitis B)	Age ≥18 yr	Three doses on a 0-, 1-, and 6-mo schedule
Pentacel (DTaP-IPV/Hib)	6 wk–4 yr	Four doses; given at 2, 4, 6, and 15–18 mo

DTaP, diphtheria, tetanus, acellular pertussis; IPV, inactivated poliovirus vaccine; Hib, *Haemophilus influenzae type b*.

There has been much controversy regarding the safety of immunization, particularly the development of neurologic sequelae after certain vaccinations. The questionable association between measles–mumps–rubella (MMR) vaccine and autism has received much press and has heightened parental anxiety toward vaccination. Both the Institute of Medicine and an AAP panel of experts have independently concluded that the increasing diagnoses of autism *cannot* be attributed to the MMR vaccine. Several comprehensive reviews have also concluded that autism is not linked to MMR (5–7). Moreover, the 1998 study linking the MMR vaccine to autism has since been retracted (8–12).

No causative association was found between diphtheria–tetanus–pertussis (DTP) vaccine and infantile spasms, sudden infant death syndrome (SIDS), or permanent neurologic injury (13). The Immunization Safety Review Committee has concluded that the evidence does not support a causal relationship between thimerosal-containing vaccines and autism or other neurodevelopmental disorders (14–16). The Committee also stated that the benefits of vaccination are proven and the widespread rejection of vaccines

would lead to an increased incidence of serious infectious diseases. These and other committee reports regarding vaccine safety can be accessed on the Institute for Vaccine Safety website (http://www.vaccinesafety.edu). Health care providers can receive the most up-to-date information electronically by signing up at www.immunize.org/subscribe and www.cdc.gov/mmwr/mmwrsubscribe.html.

There are many misconceptions about contraindications to vaccine administration. However, a few true contraindications do exist. Table 284.3 reviews common myths that should not be misconstrued as contraindications to vaccination. Several of the recommended vaccinations have precautions associated with their administration. In these cases, the physician must decide whether the benefit of the immunization outweighs the risk of complications. The contraindications and precautions associated with each vaccine are discussed in the following sections.

TABLE 284.3
Not Contraindications to Immunization

Mild local reaction (soreness, redness, swelling) to previous vaccination
Fever after previous vaccine dose
Mild acute illness with or without fever
Current antimicrobial therapy
Prematurity (infants should receive same dosage and schedule as full-term infants)
Recent exposure to infectious disease
Nonimmunized household contact
Immunocompromised or pregnant household contact
HIV infection (unless low CD4+ counts)

Diphtheria–Tetanus–Pertussis

Acellular pertussis vaccine (DTaP) has been recommended for primary immunization in the United States since 1997, as it causes fewer local and systemic reactions than the whole-cell pertussis vaccine (DTP) (13). DTaP should be given at ages 2 months, 4 months, 6 months, 15 to 18 months, and 4 to 6 years, with a booster

dose at 11 to 12 years. If the fourth dose of DTaP is delayed until after the fourth birthday, the fifth dose is not recommended.

The most common reactions to DTaP vaccine include mild local reactions (redness, induration, and tenderness at the injection site), and constitutional symptoms (fever $< 40.5^{\circ}C$, fussiness, drowsiness, crying). These manifestations usually present within several hours of vaccination and resolve spontaneously without sequelae. Seizures were fairly common after vaccination with whole-cell vaccine but occur much less commonly after administration of acellular DTaP (13). When seizures do occur, they are brief, generalized, and self-limited. The vaccine-associated seizures do *not* increase the child's risk of developing epileptic seizures or other neurologic sequelae.

Haemophilus influenzae type b

The Hib vaccines are well tolerated, with mild local skin reactions being the most common adverse event reported. Anaphylaxis after a prior dose of the vaccine or any of its components is a contraindication, and moderate or severe acute illness is a precaution to vaccination.

Hepatitis A

Hepatitis A vaccines (containing inactivated virus) first became available in the United States in 1995. Hepatitis A vaccination is recommended for all children 12 to 23 months old, given as a two-dose series at least 6 months apart. Reports estimate that protective levels of antibody after vaccination could be present for $\leq$14 to 20 years in children (13). Soreness at the injection site is the most frequently reported adverse effect after vaccination.

Hepatitis B

Recombinant hepatitis B vaccines contain hepatitis B surface antigen protein. The various vaccine products available in the United States differ in the concentration of protein, but all are 90% to 95% effective in preventing hepatitis B virus infection. Long-term studies indicate that vaccine protection lasts for at least 15 years, and no

routine booster doses are recommended at this time for children and adults with normal immune status. Universal immunization beginning at birth is now recommended. The vaccines are well tolerated, with pain at the injection site being the most common adverse effect.

Influenza

All currently available influenza vaccines are trivalent and thus contain three strains of influenza virus (two types of influenza A virus and one type of influenza B virus). One or two strains are changed yearly in anticipation of the most prevalent disease-causing strains circulating in the United States at that time. There are two types of influenza vaccines currently available. The *trivalent inactivated vaccine* (TIV), given intramuscularly or intradermally, is the more widely used. The most common side effect is soreness at the vaccination site. Fever, myalgia, malaise, and other systemic symptoms occur more commonly in those receiving the vaccination for the first time. The intradermal formulation of TIV is licensed for use in those aged 18 to 64 years. The most common adverse reactions are induration, redness, swelling, pain, and itching at the site of administration. Headache, myalgia, and malaise may also occur (13). The *live attenuated influenza vaccine* is an intranasal mist (FluMist) approved only for healthy nonpregnant persons of ages 2 to 49 years. The most common adverse effect is rhinorrhea; however, headache, emesis, fever, and myalgias may also occur. Quadrivalent live and inactivated influenza vaccines are both anticipated to be available during the 2013 to 2014 influenza season (18,19).

Vaccine protection is variable, ranging from 50% to 95% depending on the match of vaccine strain to the circulating virus strain. Yearly influenza vaccination is currently recommended for all persons aged $\leq$6 months.

Influenza vaccination with TIV has been associated with a slight increase in cases of Guillain–Barré syndrome (GBS) in adults. Although this has not been confirmed in children, development of GBS within 6 weeks of immunization with TIV should be considered a precaution to future vaccination.

**Recommendations for the influenza vaccine are constantly being updated. Please refer to http://www.cdc.gov/flu/professionals/acip/ for the most up-to-date recommendations from the Advisory Committee on Immunization Practices (ACIP).

Measles–Mumps–Rubella

There has been a dramatic decline in the incidence of measles and its complications since licensing of the first vaccine in 1963. Most recipients are immune after receiving a single dose of the live-attenuated vaccine after 12 months of age, but universal immunity is almost always conferred after two doses (13).

There was a resurgence of measles in the United States between 1989 and 1991 because of decreasing immunization rates in preschool-age children. With the renewed efforts for universal vaccination, the incidence of measles in the United States is once again low, with most cases now being seen only in immigrants from countries where measles disease is endemic.

Children may develop a transient rash or fever $\leq 39^{\circ}C$ at 6 to 12 days after vaccination with MMR or MMRV. The fever usually lasts between 1 and 5 days and presents with no other symptoms. Febrile seizures 5 to 12 days after immunization may also occur. Local hypersensitivity reactions to MMR/MMRV vaccine may occur, but anaphylaxis is rare. Transient thrombocytopenia has been reported within 2 months of vaccination and should be considered a precaution to future vaccination.

Meningococcus

Four meningococcal vaccines are currently licensed and available in the United States, the newest of which is combined with Hib and approved as a four-dose series for use in children 6 weeks through 18 months of age. The most frequent reaction to vaccination is pain and redness at the injection site. Previous anaphylaxis to the vaccine or to any of its components including diphtheria or tetanus toxoid is a contraindication to receiving further doses.

Pneumococcus

There are currently two pneumococcal vaccines licensed for use in children in the United States; PCV13 (Prevnar13) and PPSV23—(Pneumovax23)284. Mild local reactions and fever within the first 2 days after injection are the most common adverse effects reported (Table 284.4).

TABLE 284.4
Children at Risk for Invasive Pneumococcal Infections

High risk
Sickle cell disease and/or asplenia
Immunodeficiency
Chronic renal, cardiac, or pulmonary disease
Diabetes
Cochlear implants
Moderate risk
Children younger than 2 yrs of age
Children 36–59 mo in out-of-home day care
African American or American Indian children ages 36–59 mo
Low socioeconomic status
Homelessness
Chronic exposure to tobacco smoke
History of recurrent otitis media or tympanostomy tubes

Polio

Disease due to wild poliovirus has virtually been eradicated in the United States since the implementation of universal vaccination in 1979. After that, several cases of oral vaccine–associated paralytic polio (VAPP) had been reported in the United States annually. An inactivated poliovirus vaccine (IPV), which does not carry a risk of paralysis, was introduced into the routine immunization schedule in 2000. The oral polio vaccine is no longer available in the United States. IPV contains poliovirus inactivated with formaldehyde. Immunity after vaccination is expected to be lifelong. IPV is well tolerated, with no serious adverse effects reported.

Rotavirus

Two rotavirus vaccines are licensed for use among infants in the United States. A live, oral, pentavalent rotavirus vaccine (RV-5-RotaTeq) was licensed for use in the United States in 2006.

A rhesus-based tetravalent rotavirus vaccine (RotaShield) was used for routine vaccination of infants in 1998, but it was withdrawn from the market within 1 year due to its association with intussusception. Accordingly, there has been public anxiety regarding the use of current rotavirus vaccines. Some studies performed outside the United States have detected a slight increased risk of intussusception shortly after the first dose of rotavirus vaccine, but the level of risk is substantially lower than after immunization with RotaShield (13).

The most frequently reported adverse effects after vaccination are fever, diarrhea, vomiting, rhinorrhea, cough, and ear infection.

Varicella

The live-attenuated varicella vaccine was introduced in the United States in 1995 for use in patients older than 1 year who have not had varicella disease. Quadrivalent measles–mumps–rubella–varicella (MMRV) vaccine is licensed for use in healthy children 12 months to 12 years of age. The vaccines are more than 95% protective against moderate-to-severe disease. Both vaccines are given subcutaneously in two doses. The most common adverse event after vaccination is a mild local reaction with pain, redness, and swelling at the injection site. A small percentage of children may develop a mild varicella-like illness with the development of fewer lesions and lower rates of fever than nonimmunized children with varicella disease. Children who develop a postvaccination rash may rarely transmit the virus to others. There is a slightly increased risk of febrile seizures following the first dose of MMRV compared with MMR and monovalent varicella.

ED EVALUATION

The risks of natural disease in nonimmunized children should be discussed with parents. They should further be informed of the risks

and benefits associated with preventive immunization. The National Childhood Vaccine Injury Act (NCVIA) of 1986 included strict legal requirements for administering immunizations. A vaccine information statement (VIS) detailing the risks and benefits of each vaccination must be provided to the parent prior to immunization. Copies of current VISs can be obtained from the CDC, AAP, vaccine manufacturers, local health departments, or by calling the national immunization hotline. The NCVIA further requires health care personnel record in the patient's medical record the vaccine manufacturer, lot number, and date of administration, and the name and address of the person giving the vaccine. Although current VISs do not require a parent's signature, both the CDC and the AAP recommend a note be made in the patient's chart indicating the VIS was provided and discussed with the legal guardian. The AAP further recommends the site and route of administration and the expiration date of the vaccine be documented as well (13). If vaccinations are administered in the ED, emergency physicians should notify primary care providers of the immunizations given either by facsimile or by inserting a page into the child's immunization book.

Although all vaccines are considered safe and effective, some children will experience adverse reactions. Most reactions are minor and inconsequential, but some may rarely be serious and life-threatening. The most common events associated with vaccination are mild febrile and local reactions. Sterile abscesses may occur at the site of an intramuscular injection. Nerve and vascular injuries are uncommon. Serious adverse effects, such as encephalopathy and permanent neurologic damage, are rarely vaccine-associated events. The cause of a neurologic event that occurs temporally related to vaccination is often difficult to ascertain, as immunizations are given during a time when most neurologic problems first present.

Unexpected adverse events occurring soon after immunization should be reported to the Vaccine Adverse Event Reporting System (VAERS). Several similar events documented after administration of a certain vaccine can be used in conjunction to determine causation between immunization and adverse reaction. There is no time limit for reporting an adverse event. Disease that occurs in an immunized

child should also be reported to the VAERS. Reports to the VAERS can be submitted electronically (http://vaers.hhs.gov/index). The occurrence of a vaccine-preventable disease should be reported to the local or state health department.

The National Vaccine Injury Compensation Program is a no-fault system that provides compensation to people who have experienced severe or fatal vaccine complications. Claims must be filed within 36 months of the appearance of the first symptom after vaccination. All vaccines that are recommended as part of the routine childhood immunization schedule are included in the compensation program (13).

CRITICAL INTERVENTIONS

- Be aware of each child's immunization status. Do not miss an opportunity to vaccinate.
- Know contraindications and precautions to vaccinations
- Document vaccine side effects; ask about prior vaccine reactions
- Decide whether benefits of immunization outweigh risks of complications
- Report unexpected postvaccination adverse events to VAERS

DISPOSITION

When a severe or unexpected immunization reaction is suspected, consultation with a pediatrician, neurologist, or infectious disease expert should be obtained. Severe unexpected vaccine complications must be reported to the VAERS. Children with significant neurologic findings, anaphylaxis, or other serious vaccine complications should be hospitalized. Transfer to a tertiary pediatric facility should be considered if further subspecialty consultation or intensive care is needed. The child's primary physician should be notified of the possible immunization reaction.

Common Pitfalls

- Minor febrile illness is not a contraindication to routine immunization.

- Current antimicrobial therapy is not a contraindication to vaccination.
- HIV infection is not an absolute contraindication to live vaccination.
- Mild local and febrile reactions are not contraindications to further doses of vaccine.
- Do not automatically attribute fever occurring after immunization to vaccination. Thoroughly examine the child for a treatable focus of infection.
- Allergic reactions after vaccination are rare; always consider other causes.

CHAPTER 285 Nursemaid's Elbow

Evan J. Weiner

CLINICAL PRESENTATION

Radial head subluxation, also known as *nursemaid's elbow,* is a common orthopedic injury occurring in early childhood. The peak incidence is in the toddler years; however, the condition also occurs in the first year of life and has been described as late as age 6 (1–3). The left arm is more commonly affected, as are females (1,3–5).

The most commonly described mechanism of injury is that of axial traction on the extended arm usually occurring when an adult pulls up or swings a child by the arm (2–4,6,7). However, a history of this pulling mechanism may not be present in up to half the cases (2,3,7). Occasionally the history of a fall may be provided (2).

Children with nursemaid's elbow present because of refusal to use the affected arm and will be noted to hold the arm at their side with the forearm in a pronated position. Because of their young age, they are often unable to localize their pain. The examiner should have difficulty detecting any point of tenderness but will note that the child resists and has pain with any movement at the elbow joint. It is helpful to use good distraction tools when examining these young anxious children. It is important to note that patients with nursemaid's elbow do not have any swelling, warmth, or ecchymosis. If these findings are present, radial head subluxation is unlikely to be the cause.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of decreased arm use in a child includes, but is not limited to, fractures of the clavicle, humerus or forearm, septic joint, osteomyelitis, and brachial plexus injury. The presence of fever, swelling, bruising, or other skin changes involving the affected arm is an indication for radiography and possible further laboratory studies.

ED EVALUATION

The history elicited from the caregiver should include the timing and mechanism of injury, the presence of fever, and any prior episodes of a similar problem with the arm. Any history of chronic medical conditions predisposing the child to bone or joint disease should also be sought (e.g., hemophilia, sickle cell anemia, osteogenesis imperfecta, immune disorders), as this may indicate another more likely cause.

During examination of the upper extremity, it is often helpful to have the child placed on the parent's lap in a sitting position facing the examiner. Before touching the child, produce a toy or colorful object to see whether the child will reach for it with each arm. Visually inspect the arm for any swelling, skin changes, or signs of trauma. It may be helpful to compare one arm to the other. Begin with palpation of the bones, beginning with the clavicle and working downward toward the hand, noting any areas of particular tenderness or warmth. Assess distal pulses and perfusion. Sensation and motor function should also be assessed if the child is able to cooperate with a neurosensory examination.

Radiographs should be performed prior to reduction attempts in cases in which aspects of the history (e.g., witnessed direct trauma to the upper extremity) and examination findings (e.g., swelling, bruising, warmth over the joint) suggest that infection or fracture are more likely than radial head subluxation. Patients who present with a history and examination findings consistent with nursemaid's elbow need not undergo radiography prior to reduction attempts. Not uncommonly, a child with a nursemaid's elbow who is sent for

radiographs of the arm will undergo an incidental reduction in the radiology suite during the repositioning of the arm for the study.

KEY TESTING

Although radiographs are not needed in classic presentations of nursemaid's elbow, radiographs should be performed in patients with atypical examination findings (e.g., swelling, ecchymosis, redness, fever, point tenderness). These radiographs should include three views of the elbow, including a good quality 90-degree lateral view. In general, radiographs should also include a joint proximal and distal to the injury.

- Three-view elbow radiographs, including 90-degree lateral
- Radiographs of a joint above and below injury (e.g., two-view forearm and two-view humerus)

ED MANAGEMENT

There are two different methods commonly used for reducing a nursemaid's elbow. Prospective studies comparing the two methods reveal that the hyperpronation technique has a significantly higher initial success rate than the supination/flexion technique (1,4). Furthermore, there is growing evidence that the hyperpronation method is less painful for the patient (1,8). Both techniques are described here.

Hyperpronation Technique

The hyperpronation method involves the examiner cradling the child's elbow with one hand (with thumb or forefingers overlying the radial head) while the examiner's other hand is used to hyperpronate the child's forearm by holding and turning the child's hand into a hyperpronated position (Fig. 285.1). With successful reduction, a "click" will be felt by the examiner. The child usually experiences some momentary discomfort during the procedure.

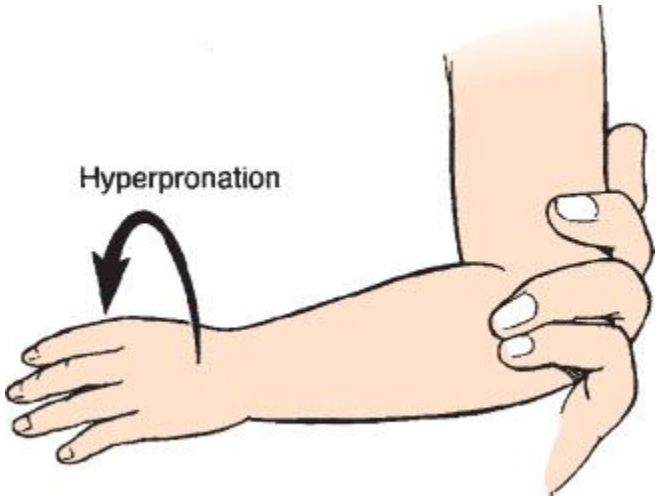

FIGURE 285.1 Hyperpronation technique. Pronation at the wrist. (From Macias CG, Bothner J, Wiebe R. A comparison of supination/flexion to hyperpronation in the reduction of radial head subluxations. *Pediatrics.* 1998;102:e10, with permission.)

Supination/Flexion Technique

The supination/flexion technique involves the examiner cradling the child's elbow with one hand (again with thumb or forefingers over the radial head) and with the other hand supinating the patient's hand completely until the palm faces the ceiling. The examiner then fully flexes the child's elbow by bringing the supinated hand up toward the shoulder (Fig. 285.2). With successful reduction, a "click" will often be felt. The child experiences momentary discomfort at the time of the procedure.

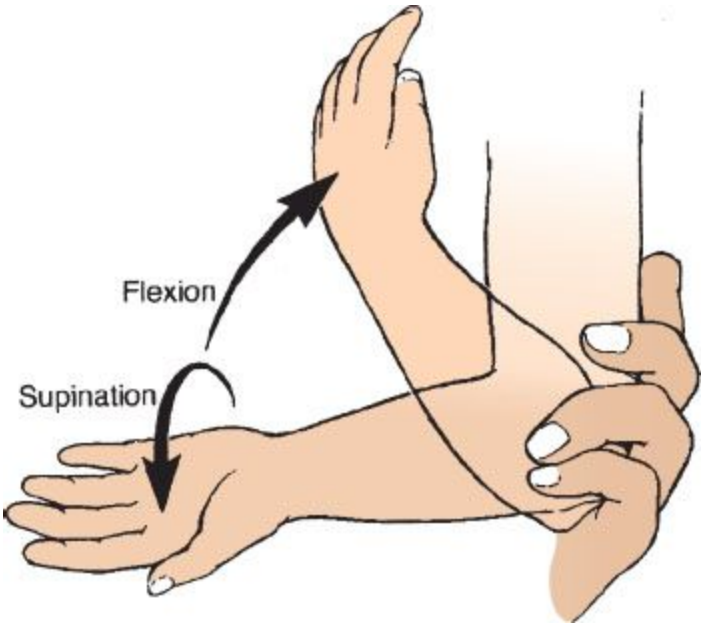

FIGURE 285.2 Supination/flexion technique. Supination at the wrist followed by flexion at the elbow. (From Macias CG, Bothner J, Wiebe R. A comparison of supination/flexion to hyperpronation in the reduction of radial head subluxations. *Pediatrics*. 1998;102:e10, with permission.)

Regardless of which reduction technique is used, it may be 15 minutes or longer before the child begins to use the arm normally again. Again, the examiner should see if the child can reach for a toy or similar object. A failed reduction attempt should be followed by a second attempt using either the same or alternate technique. This second attempt often meets with success (4). After two or three failed reduction attempts, radiographs of the upper extremity should be obtained to help exclude fracture or other pathology as the cause of the child's symptoms.

DISPOSITION

The child with a successfully reduced nursemaid's elbow does not need specific follow-up with the primary caregiver unless symptoms (pain or disuse of the arm) return. Parents and caregivers should be cautioned about refraining from any activity that involves pulling

on the child's arm, since the condition recurs in about one-fourth of children who have experienced at least one episode (5).

The patient who does not respond to reduction attempts will require splinting of the arm with a posterior long-arm splint and orthopedic consultation.

Common Pitfalls

- Attempting a nursemaid reduction in any child who has swelling, ecchymosis, or deformity of the extremity, as these findings are not consistent with a nursemaid's elbow and manipulation could result in further injury and unnecessary pain.
- Assuming that a patient cannot have a nursemaid's elbow simply because there is not a clear history of a pull on the child's arm; this history is lacking in a large percentage of cases (2).

CHAPTER 286
Renal Emergencies

Madeline Matar Joseph and Carmen J. Martinez

Renal emergencies may present with a wide spectrum of acuity and may be the first identified manifestation of significant underlying systemic disease. This chapter focuses on hematuria and two important renal diseases, glomerulonephritis (GN) and nephrotic syndrome.

HEMATURIA AND GLOMERULONEPHRITIS

CLINICAL PRESENTATION

Hematuria is the presence of blood in the urine, which can be macroscopic (visible to the naked eye) or microscopic. Microscopic hematuria represents one of the most frequently encountered genitourinary abnormalities in children. There are many causes of hematuria (1). It is important to first determine the source of bleeding in the presenting child. In infants, blood on the diaper can originate from the vagina or rectum and be confused with hematuria. The “red diaper syndrome” in infants has two causes: One is a group of healthy infants whose soiled diapers develop a red color after 24 to 36 hours, which is attributed to *Serratia marcescens;* the second is due to urate crystals. The former is rarely seen, owing to the popularity of disposable diapers. In the menstruating girl, vaginal bleeding can be confused with urinary blood. It is often necessary to obtain a catheterized urine specimen to determine the source of the bleeding. Up to 50% of cases of hematuria in children (more so than adults) are glomerular in origin. Glomerular bleeding tends to be associated with cola-colored urine (30% of patients), whereas lower

tract bleeding colors the urine red or pink. The passage of blood clots in the urine usually points to the bladder or urethra as the source of bleeding.

Acute glomerulonephritis (AGN) results from immunologic effects on the glomerular tissue and is divided into three broad categories: (1) Postinfectious, (2) intrinsic renal disease, and (3) systemic disease (Table 286.1). Poststreptococcal acute glomerulonephritis (PSAGN) is one of the most common causes. Poststreptococcal GN is most common in children aged 5 to 12 years and uncommon before the age of 3 years. PSAGN is known to follow infections of the skin (part of an epidemic, summer time, particularly in the southern regions of the United States accounting for two-thirds of cases) or pharyngitis with certain nephrogenic strains of streptococci, which are virtually always group A streptococci (2,3). The incidence of clinically detectable GN during an epidemic is up to 10% of children with pharyngitis and 25% of children with impetigo. One study reported a change in the epidemiology of PSAGN and found that pharyngitis has replaced impetigo as the predominant cause of PSAGN (4).

TABLE 286.1
Causes of Glomerulonephritis

Postinfectious	Renal Systemic
Streptococcus	*Membranoproliferative GN*
	Wegener granulomatosis
GAS	Type I and II
	Hypersensitivity vasculitis
Other bacteria:	*IgA nephropathy* (Berger disease)
	Cryoglobulinemia
Staphylococcus, mycobacteria, salmonella	*Idiopathic rapidly progressive GN*
	Systemic lupus erythematosus
Viral: CMV, Coxsackie, EBV, hepatitis	Type I: Antiglomerular basement membrane
	Polyarteritis nodosa rubella, mumps disease
Fungal:	Type II: Mediated by immune complexes
	Henoch–Schönlein purpura
Coccidioides immitis	Type III: Antineutrophil cytoplasmic antibodies
	Goodpasture syndrome
Parasite: Plasmodium spp, Schistosoma mansoni, Toxoplasma gondii, filariasis, trichinosis, trypanosomes	

CMV, cytomegalovirus; EBV, Epstein–Barr virus.

Characteristically, there is a latent period between the onset of the streptococcal infection and the onset of nephritis that ranges from 8 to 14 days for pharyngitis and 14 to 21 days for skin infections (2). The onset of GN less than a week after streptococcal infection is highly suggestive of pre-existing renal disease (5). Of note, hypertension under these circumstances usually does not require antihypertensive treatment and resolves with treatment of associated fluid retention.Table 286.2 includes the clinical manifestations in PSAGN in order of frequency.

TABLE 286.2
Clinical Symptoms of Glomerulonephritis

Most Frequent	Less Frequent
Edema (periorbital most common)	*Urinary tract syndrome* (Flank pain, dysuria, frequency)
Hematuria (Microscopic to gross)	*Circulatory congestion* (Mild CHF, pulmonary edema
Hypertension (Mild–moderate) in 75% of patients	*Hypertensive encephalopathy*
Oliguria	*Acute renal failure*
Nonspecific systemic symptoms (Anorexia, nausea, fever, malaise, abdominal pain)	

CHF, congestive heart failure.

Dysuria, frequency, or abdominal pain suggests a urinary tract infection (UTI). A history of recent trauma, strenuous exercise, menstruation, or bladder catheterization or of masturbation, excessive bicycle riding, or urethral foreign body insertions (particularly in adolescents) may account for transient hematuria and exclude the need for further workup. A recent or earlier history of renal colic or passage of a stone in the urine and a family history of hypercalciuria and renal stones should be elicited. Associated symptoms such as hemoptysis (Goodpasture syndrome) or the triad of sinusitis, AGN, and pulmonary infiltrates (Wegener granulomatosis) could aid in the diagnosis. History should include the use of antibiotics, chemotherapy, radiation for malignancies, exposure to tuberculosis, and the use of over-the-counter medications, which may cause interstitial nephritis. Umbilical catheterization in the neonatal period can cause renal vein or artery thrombosis, which may result in hematuria (6). A family history of hearing deficits and renal failure can lead to the diagnosis of Alport syndrome. Other diseases that carry a genetic origin include systemic lupus erythematosus (SLE), sickle cell anemia, hemophilia, and other coagulation factor deficiencies. Nephrolithiasis and IgA nephropathy also have a familial association.

Acute complications may arise from hypertension secondary to acute renal dysfunction. Hypertension is seen in 60% of such patients and is associated with hypertensive encephalopathy in 10% of cases. Although the neurologic sequelae are often reversible with

appropriate management, severe prolonged hypertension can lead to intracranial bleeding. Other potential complications include heart failure, hyperkalemia, hyperphosphatemia, hypocalcemia, acidosis, seizures, and uremia. Acute renal failure may require dialysis with the acute phase generally resolving within 6 to 8 weeks (2). Although urinary protein excretion and hypertension usually normalize by 4 to 6 weeks after onset, persistent microscopic hematuria can persist for 1 to 2 years after the initial presentation.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for childhood hematuria can be remembered by using the alphabetical sequence A through I (see Table 286.3) (1).

TABLE 286.3
The Differential Diagnosis of Childhood Hematuria

***A*natomy**/vascular (renal cysts, arteriovenous malformations, obstruction with hydronephrosis)

***B*oulders** (renal stones, hypercalciuria, and hyperuricosuria)

***C*ancer** (Wilms tumor or adenocarcinoma and infiltration of the kidney by leukemia or solid tumors)

***D*rugs/Dehydration** (over-the-counter or illicit drugs, methicillin, cyclophosphamide, anticoagulants)

***E*xercise**-induced hematuria

***F*oreign body, familial** (Alport) or **factitious**

***G*lomerulonephritis (GN):** Primary: Poststreptococcal GN, IgA nephropathy (Berger Disease), membranoproliferative GN. Secondary GN: HSP, HUS, SLE

***H*ematology** (hemoglobinopathy, coagulopathy)

***I*nfection** (cystitis caused by adenovirus, tuberculosis, schistosomiasis in patients with recent travel to the Middle East or Africa)

ED EVALUATION

In the absence of gross hematuria, the primary tool for hematuria screening is a urine dipstick. Blood +1 and greater is considered positive. The dipsticks used for detection of blood in the urine are very sensitive in detecting red blood cells (RBCs) and minute amounts of free hemoglobin and myoglobin. All positive dipstick

screens should be confirmed by a microscopic examination of the urine to confirm the presence of RBCs. Causes of false-positive dipstick reactions include myoglobinuria, (rhabdomyolysis); hemoglobinuria (seen in conditions causing hemolysis); oxidizing contaminants, such as bacterial peroxidases from a UTI; delay in reading the dipstick; and interfering compounds, such as beets or aniline dyes. A false-negative dipstick result can occur in urine with high specific gravity and in urine containing large amounts of reducing substances such as ascorbic acid. Screening dipstick urinalyses are still being performed on school-aged children despite the fact that the American Academy of Pediatrics is no longer recommending it for school-aged children to detect chronic kidney diseases (7,8).

The physical examination of the patient with hematuria is largely nonspecific; however, an accurate blood pressure is essential. The presence of elevated blood pressure should alert the clinicians to the possibility of a more severe underlying condition. The height and weight of the child should also be plotted carefully to assess for failure to thrive associated with long-standing acidosis or chronic renal insufficiency. A funduscopic examination should be performed, looking for evidence of long-standing hypertension or lenticonus as seen in Alport syndrome. In children, periorbital edema is the most common location of edema associated with glomerular disease. The chest should also be examined for signs of fluid overload. Costovertebral angle tenderness may indicate a UTI or recent trauma can be detected by findings of flank bruises and pain. Examining the abdomen for masses is critical for the identification of malignancies (Wilms tumor), polycystic kidneys or hydronephrosis. The examination of the skin and joints can give evidence of arthralgias and pallor or rashes. This may be significant in diseases such as hemoglobinopathies (leukemia, Henoch–Schönlein purpura, petechial or purpuric lesions on the lower extremities), and SLE (malar rash). The genital examination should be included to identify abuse or trauma, discharge, and meatal stenosis, all of which can cause hematuria.

Renal imaging should be performed (computed tomography [CT] with IV contrast) for any child with gross hematuria and a history of abdominal trauma to detect and grade any renal injury. Gross hematuria is not the only presentation for significant renal injuries. Significant injuries may present with either microscopic hematuria or with a normal urine analysis. Therefore, imaging decisions for the diagnosis and grading of renal injuries should not be based solely on urine analysis results without consideration of clinical status or mechanism of injury (9). Patients presenting with gross hematuria after minimal-force blunt abdominal trauma should be considered at risk for pathologic lesions of the urinary tract. The diagnostic and therapeutic approach to blunt renal trauma should be modified in these cases (10). Some authors recommend a CT scan of the abdomen and pelvis should be performed in patients with 50 or more RBCs on urinalysis, hypotension at the time of emergency department (ED) presentation, or if there is a serious mechanism of injury such as high-speed motor vehicle accident with evidence of deceleration injuries (11). If blood is noted at the urethral meatus, a retrograde urethrogram must be done prior to catheterization to verify urethral integrity.

A urine culture must be sent if dysuria, urinary frequency, or the presence of systemic signs (fever, vomiting, diarrhea, and abdominal pain) suggests the possibility of a UTI. UTIs are the most common cause of macroscopic hematuria, and a third of UTIs are associated with hematuria; making the urine culture especially important in children with white blood cells on microscopic urinalysis (1). If the culture is negative and signs and symptoms are strongly suggestive of cystitis, alternative causes include adenovirus or a chemical cystitis due to bubble bath. The child with gross hematuria and sudden colic flank or abdominal pain associated to nausea and vomiting should raise the suspicion for urolithiasis. In younger patients, symptoms can be less specific. In this case, the initial workup consists of radiologic imaging, urinalysis, and urine culture. Radiologic imaging consists of an abdominal x-ray, a renal sonogram or noncontrast abdominopelvic spiral CT. Of these, the most sensitive and specific for diagnosis is the noncontrast spiral CT (12).

Gross hematuria and the presence of proteinuria suggest GN. Proteinuria should not exceed 2+ if the only source of protein is from the blood. Pertinent laboratory evaluation includes serum electrolytes (potassium), renal function (BUN, creatinine) complete blood count (for hemolytic–uremic syndrome), and culture from the throat and skin should be sent to isolate a nephrogenic strain of *Streptococcus*. Hematuria is the most consistent urinary abnormality in AGN, but the urinalysis can be normal. Rising antistreptolysin-O (ASO) titers suggest previous recent streptococcal infection; however, the ASO may not rise after pyoderma. Therefore, anti-DNAse B is the best single test to detect recent streptococcal infection. The complement C3 level is low in acute poststreptococcal GN, membranoproliferative GN, and SLE but returns to normal in 6 to 8 weeks (2). Complement levels and antinuclear antibody tests may be helpful if a diagnosis of underlying systemic disease is being entertained. Evaluation also includes serum creatinine, potassium concentrations, and chest radiographs, which may reveal cardiomegaly, pulmonary edema, pleural effusions, and edema of the soft tissues.

Less common causes of gross hematuria include hypercalciuria, nephrocalcinosis, sickle cell trait, and glomerular basement membrane defects. Diagnosis begins with a urine Cr/Ca ratio or a 24-hour urinary calcium excretion, serum creatinine, and renal sonography. Consultation with a pediatric nephrologist is recommended.

KEY TESTING

- Urinalysis, dipstick for blood and microscopic evaluation
- Urine culture if infection is suspected
- CT or US in cases of trauma or urolithiasis
- BUN, creatinine, CBC
- Culture of skin lesion, throat culture, ASO titers for suspected GN
- Complement levels and antinuclear antibody for suspected collagen vascular disease

ED MANAGEMENT

The patient with hematuria should be managed according to the etiology of the disease condition. Asymptomatic hematuria does not need acute management in the ED with the exception of UTIs. Acutely emergency physicians must address pain in the uncomfortable child. Nonsteroidal anti-inflammatories and/or narcotics can be used for pain control related to urolithiasis. Ketorolac has been used for renal colic, but contrary to the adult literature, there are no studies evaluating its effectiveness in children.

A recent Cochrane review compared different antibiotic agents, routes, frequencies, and durations of therapy in children aged 0 to 18 years with proven UTI and acute pyelonephritis. Twenty-three studies (3,295 children) were eligible for inclusion. No significant differences were found in duration of fever and persistent renal damage at 6 months between 10- and 14-day oral antibiotic therapy and 3-day IV therapy followed by 10-day oral therapy. Therefore, children with acute pyelonephritis can be treated with oral antibiotics (cefixime, ceftibuten, and amoxicillin/clavulanic acid) or with short courses (2 to 4 days) of IV therapy followed by oral therapy. If intravenous therapy is chosen, effective agents include ceftriaxone, cefotaxime, ampicillin, and gentamicin; single daily dosing with aminoglycosides is considered safe and effective (13). Patients aged 2 months to 2 years with their first febrile UTI can be treated with a second- or third-generation cephalosporin or sulfamethoxazole-trimethoprim (SMZ-TMP) (13–15).

In most cases of PSAGN much of the treatment is supportive, there is no specific therapy influencing healing of glomerular lesions. Antibiotics do not alter the course of the disease but may decrease the spread of nephrogenic strains of *Streptococcus* in patients with positive cultures. Prompt treatment of hypertension, or hyperkalemia is indicated for the child in acute renal failure. This may include pharmacologic treatment of hyperkalemia and fluid restriction or diuretics (16). As many as 60% of these patients will have hypertension, with up to 10% having hypertensive encephalopathy presenting with headache, nausea, vomiting, seizures, and transient

cortical blindness (2). For hypertensive emergencies in children with PSAGN, therapy should be gradual and controlled. Hypertensive encephalopathy is a hypertensive emergency therefore because of their rapid onset of action diazoxide, hydralazine, labetalol, loop diuretics, and calcium channel blockers may be necessary. Overly aggressive blood pressure correction by more than 20% to 25% can contribute to decreased cerebral perfusion and potential hemorrhage or stroke.

In patients with nonstreptococcal GN, the nephrology consultant may recommend corticosteroids or cytotoxic agents.

Less common causes of hematuria can be pursued in the ED as resources allow and based on level of suspicion raised by the history and physical examination (17,18). Conditions requiring advanced workup (Table 286.4) should be referred to a pediatric nephrologist or urologist.

TABLE 286.4
Evaluation of the Child with Hematuria

Initial evaluation of child with hematuria
History/family history/physical examination
Urinalysis with microscopy, protein measurement
Red blood cell morphology
Urine culture
Calcium–creatinine ratio
Sickle cell screen, if applicable
Complete blood count, creatinine and blood urea nitrogen levels
Urine of first-degree relatives
Renal ultrasound
Advanced evaluation of child with hematuria
Complement level (membranoproliferative, SLE, postinfectious GN) Antistreptolysin-O and anti-DNAase B (Acute poststreptococcal glomerulonephritis)
Antinuclear antibody (SLE)
Audiogram (Alport syndrome)
Antiglomerular basement membrane antibodies
Antineutrophil cytoplasmic antibodies (Active crescenteric glomerulonephritis)
Tuberculosis testing
Renal biopsy

SLE, systemic lupus erythematosus.

CRITICAL INTERVENTIONS

- When there are signs and symptoms of UTI, a urine culture should be sent regardless of the results of the urinalysis.
- The decision to order renal imaging after blunt trauma should be based on clinical status history and mechanism of injury and not on the urinalysis alone.

DISPOSITION

Hospitalization is necessary for the following patients with UTI: Patients who are septic, ill appearing, have signs of urinary obstruction or significant underlying disease, who are unable to tolerate adequate oral fluids or medications, infants younger than 2 months with febrile UTI (presumed pyelonephritis), all infants younger than 1 month with suspected UTI even if afebrile.

Referral to a pediatric nephrologist should occur if the child has gross hematuria, a coexistent significant proteinuria, hypertension,

abnormal kidney function tests, persistent hypocomplementemia, findings suggestive of systemic disease, or a family history of GN, nerve deafness, chronic renal failure, end-stage renal disease, or familial hematuria. If parental anxiety is high, referral to a pediatric nephrologist may help alleviate compounding fears and serve as additional reassurance to the family that dangerous and treatable conditions have been ruled out. Parents are often concerned their child is losing large amounts of blood based on the color of the urine; they should be reassured that as little as 1 mL of blood in 1 L of urine can make the urine red (19).

Patients with newly diagnosed renal disease should be admitted with pediatric nephrology consultation to monitor for possible complications, such as hypertension, hyperkalemia, and acute renal failure.

It is important to remember the most common causes of microscopic hematuria without casts or proteinuria are benign and do not require treatment. The prognosis for these children is very good while a poor prognosis tends to be associated with proteinuria at presentation, persistent hematuria, and hypertension.

Common Pitfalls

- Failure to perform a urine dipstick and urinalysis to confirm the presence of blood in the patient with "red urine." This can lead to unnecessary further laboratory testing.
- Failure to obtain relevant historical information such as a history of recent pharyngitis, trauma, or renal stones
- Failure to detect proteinuria, hypertension, or subtle signs of fluid overload
- Failure to include AGN in the differential diagnosis of hematuria, particularly when there are other signs such as edema

NEPHROTIC SYNDROME

CLINICAL PRESENTATION

The nephrotic syndrome is characterized by proteinuria and hypoalbuminemia that is often associated with edema and hypercholesterolemia. A small number of patients may also have hypertension, hematuria, and decreased glomerular filtration rate. This combination of clinical findings may be found alone or in association with a number of systemic illnesses such as diabetes, amyloidosis, and lupus erythematosus or viral infections (e.g., Hepatitis B, Hepatitis C, and HIV) or preeclampsia (19). The primary pathophysiologic issue in nephrotic syndrome is the increased permeability of the glomerular capillary wall to plasma proteins leading to an excessive albuminuria.

The incidence of nephrotic syndrome is two to seven new cases per 100,000 children (15 years of age and younger) per year. The peak age of onset is 2 to 3 years, and 75% of children are younger than 10 years (19). The nephrotic syndrome is categorized into primary (>90% of cases) and secondary forms (Table 286.5). Minimal-change nephrotic syndrome is the most common form accounting for 80% to 85% of primary cases, followed by focal segmental glomerulosclerosis and membranoproliferative glomerulonephropathy (19).

TABLE 286.5
Etiology of Nephrotic Syndrome

Primary/minimal change
Congenital: Steroid responsive, Steroid resistant
Secondary
Associated with systemic disease: SLE, Henoch–Schönlein purpura, sickle cell disease, diabetes mellitus, lymphoma, Berger disease/IgA nephropathy, amyloidosis
Postinfectious glomerulonephritis: Syphilis, malaria, HIV, CMV, toxoplasmosis, hepatitis
Associated with medications: NSAIDS, heroin, gold salts, tridione
Associated with toxins/allergens: Bee sting, poison oak, vaccinations, food allergy

CMV, cytomegalovirus; NSAID, nonsteroidal anti-inflammatory drug; SLE, systemic lupus erythematosus.

A renal biopsy revealing minimal glomerular abnormalities, yields a better prognosis and 92% of these patients will respond to corticosteroid therapy (20). Regardless of the histopathologic abnormalities, edema is the most prominent clinical manifestation of the nephrotic syndrome in most children. This may be initially seen in the periorbital area and often follows a flu-like illness so it may often be confused with allergies or sinusitis. It is pitting in nature and typically seen in dependent areas, so facial swelling may be observed in the morning, whereas lower extremity edema is exhibited in the evenings. Oliguria may be seen but is more common in relapses (21). Other symptoms such as anorexia, abdominal pain (thought to be due to bowel wall edema), vomiting, diarrhea, and fatigue can also be present. With anasarca and abdominal distention, patients may have respiratory distress, umbilical and inguinal hernias, and/or rectal prolapse. Pleural effusions and, less often, pericardial effusions may be present. Ascites has been described and can be a source of infection in children presenting with fever. On rare occasions, a child may present with signs of thrombosis secondary to a hypercoagulable state associated with nephrotic syndrome.

The initial of nephrotic syndrome, and subsequent relapses, may follow a viral upper respiratory tract infection. Microscopic hematuria occurs in approximately 20% of children with minimal-change nephrotic syndrome and in 50% of those with membranoproliferative disease. The presence of macroscopic hematuria should prompt investigation for underlying causes. Blood pressure is usually normal in minimal-change nephrotic syndrome but hypertension in up to 13% of patients (above the 98th percentile for age) has been reported. Persistent hypertension is uncommon and is suggestive of a diagnosis other than minimal-change nephrotic syndrome.

DIFFERENTIAL DIAGNOSIS

The complete differential diagnosis of nephrotic syndrome is listed in Table 286.5. Although nephrosis may be the presenting symptom in the secondary forms, there is usually accompanying evidence related

to the underlying diagnosis. This includes a number of disorders commonly seen in the pediatric ED including, Henoch–Schönlein purpura, sickle cell disease, diabetes mellitus, lymphoma, HIV, hepatitis, bee sting, poison oak, vaccinations, and food allergies among others.

ED EVALUATION

Laboratory findings diagnostic of the nephrotic syndrome include (1) proteinuria: >40 mg/m^2/d ($>2+$ on urine dipstick) and spot urine protein to creatinine ratio greater than two, (2) hypoproteinemia: Serum albumin <2.5 g/dL, (3) hyperlipidemia with elevated serum levels of triglycerides, cholesterol, and total lipids, (4) normal serum creatinine, (5) normal or slightly elevated serum blood urea nitrogen, and (6) increased hemoglobin (seen frequently owing to hemoconcentration). Secondary findings include hypocalcemia (with a normal ionized fraction), hyperkalemia, hyponatremia, and hypercoagulability (22).

Many children with nephrotic syndrome are apparently healthy and have edema as their only obvious presenting abnormality. A thorough physical examination is indicated; however, to assess for respiratory difficulties secondary to ascites and pleural effusions or complications related to infection and thrombotic phenomena. The presence of edema can be deceptive, giving the impression of fluid overload when, in fact, many patients are, secondary to their hypoproteinemia, intravascularly volume depleted.

Depending on the clinical findings, other laboratory studies may be performed such as antinuclear antibodies, ASO titer, syphilis serology, hepatitis B surface antigen, testing for the human immunodeficiency virus, and skin testing for tuberculosis. There are no radiographic studies routinely recommended, but a chest x-ray may be helpful in evaluating for pleural effusions.

KEY TESTING

- Urinalysis
- Serum albumin
- Serum electrolytes, including Ca

- CBC
- Serum triglycerides, cholesterol, and total lipids

ED MANAGEMENT

Typically, the treatment of the initial presentation of nephrotic syndrome is not an emergency; however, children are admitted to the hospital for therapy and further testing. Patients who have relapsed may present to the ED but may not require admission. General measures to treat the edema of nephrotic syndrome include salt restriction (no-added-salt diet) and occasionally diuretics. Furosemide (Lasix) is the diuretic of choice for nephrotic patients with severe discomfort due to fluid retention. It is given orally or intravenously in a dose of 1 to 2 mg/kg and may require giving an infusion of salt-poor albumin for optimal benefit. A useful regimen is to give furosemide intravenously, then 1 g/kg of 25% salt-poor albumin solution intravenously over 2 hours followed by a second dose of furosemide at the end of the infusion. Patients should be observed closely for hypotension or hypertension. Diuretics should be used cautiously, given the high risk of intravascular volume depletion and thrombosis. Some patients will require thoracentesis for relief of respiratory distress secondary to pleural effusions. To avoid the risk of peritonitis secondary to paracentesis the procedure should be reserved for ascites causing respiratory compromise.

Treatment consists of prompt restoration of the intravascular volume by rapid intravenous fluid administration preferably albumin containing solution. In addition, patients presenting with hypovolemic shock require hospitalization for close fluids and electrolytes monitoring following the initial fluid resuscitation.

Infections and related complications account for up to 70% of deaths in patients with nephrotic syndrome. Because of relative immune compromise they are at high risk of invasive *Streptococcus pneumoniae* infections. These patients are also susceptible to gram-negative organisms such as *Escherichia coli, Pseudomonas,* and *Haemophilus influenza* and at risk for severe varicella infections. Therefore, febrile children with nephrotic syndrome may need to be

admitted to the hospital for treatment with broad spectrum antibiotics.

Hypoalbuminemia leads to a decrease in protein-bound calcium, but ionized calcium levels can also be decreased secondary to excessive loss of vitamin D–binding protein in the urine and decreased calcium absorption. Symptomatic hypocalcemia is rare; however, bone demineralization and osteomalacia may occur and occasionally, a patient will present to the ED with tetany or muscle cramps. Such a patient should be placed on a cardiac monitor and given an initial dose of 0.5 to 1 mL/kg of a 10% solution of calcium gluconate intravenously over 3 to 5 minutes. Calcium gluconate is preferable to calcium chloride because it is less sclerosing to the veins. When symptoms are relieved, calcium gluconate may be added to the intravenous solution at a dose of 100 mg of elemental calcium/kg/d or administered orally (10% calcium gluconate contains 9-mg elemental calcium/100 mg of the salt).

Increased risk of vascular thrombosis is a rare but serious complication of the nephrotic syndrome. Routine anticoagulation is generally not recommended; however, a patient with evidence for thrombosis or additional risk factors (e.g., prolonged immobility), most likely will warrant anticoagulant medication. Renal vein thrombosis should be suspected in any patient with acute flank pain, renal enlargement, hematuria, unexplained deterioration in renal function, oliguria, or renal failure.

Corticosteroid therapy is cornerstone of treatment for nephrotic syndrome in patients with no contraindications to the use of high-dose steroids (e.g., active bacterial infection or positive tuberculin skin test) (19). The typical starting dose is 2 mg/kg/d for the first 4 to 6 weeks. Typical side effects include cushingoid faces, increased appetite, and hirsutism, which subside with decreasing doses (22). The majority of patients (~90%) will experience complete clearing of their urine on this regimen. Maintenance therapy (with slow tapering of the steroid dose) is then continued for a total of about 28 weeks, which is associated with a reduced risk of relapse. Nonsteroidal agents, such as cyclophosphamide or cyclosporine, are sometimes used in steroid-resistant patients (19). New

immunosuppressive agents, like calcineurin inhibitors have less adverse effects while inducing and maintaining remission, have also been recommended for steroid-resistant patients (23).

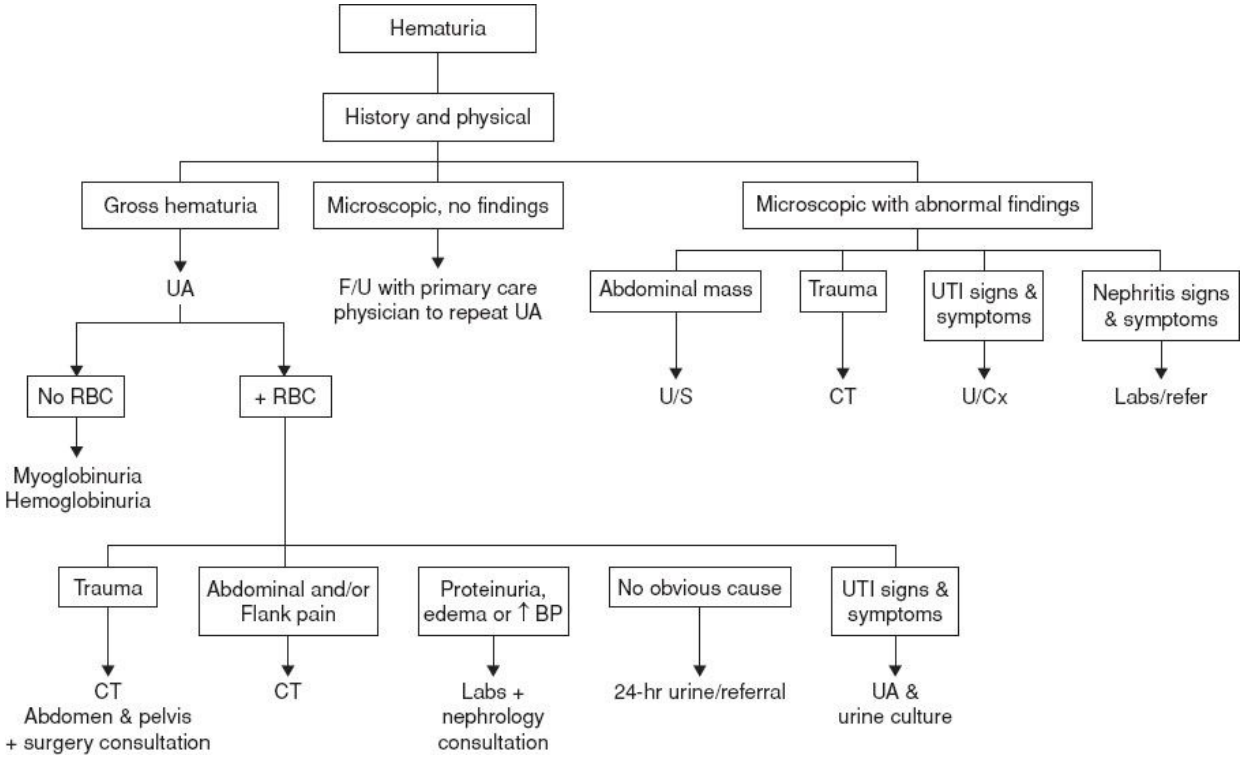

FIGURE 286.1 Approach to the diagnosis of hematuria in children.

CRITICAL INTERVENTIONS

- Patients with nephrotic syndrome may present with edema despite being intravascularly volume depleted. Diuretics should be used with caution to avoid severe hypovolemia.
- Overaggressive correction of hypertension can be dangerous, and patients must be monitored closely during treatment. A continuous infusion of nitroprusside or labetalol allows titration to desired effect.

DISPOSITION

Most children with new-onset nephrotic syndrome are admitted to the hospital for initiation of steroid therapy and aggressive education of the patient and family. A thorough history regarding tuberculosis

exposure and a chest x-ray should be performed in the ED. If these are negative, steroid therapy may be initiated. Children presenting with a relapse may be discharged to home if stable. Children older than 6 years and those with hypertension, hematuria, or evidence of impaired renal function should be admitted for further evaluation to determine the underlying cause of their disease. Mild edema may be treated with salt restriction at home. Discharge instructions should include warnings regarding fever, tachypnea, abdominal pain, chest pain, vomiting, increasing edema, and decreasing urine output.

Common Pitfalls

- Incorrectly diagnosing periorbital edema as allergy related or due to sinusitis
- Overaggressive treatment of edema in nephrotic syndrome
- Overaggressive treatment of hyponatremia in nephrotic syndrome
- Failing to take seriously fever or other signs of infection in children with nephrotic syndrome. These patients are relatively immune compromised, even before initiation of steroids.

CHAPTER 287 Genitourinary Disorders

Genevieve Santillanes and Marianne Gausche-Hill

Pediatric genitourinary and gynecologic evaluations pose specific challenges to the emergency practitioner. The physician must incorporate knowledge about stages of development, likely diagnoses for different age groups, and the patient's specific history to tailor an appropriate examination. Any child presenting with abdominal pain should undergo a genitourinary examination. In addition, the emergency physician should maintain a high index of suspicion for sexual abuse as children who are abused may present with unusual or vague complaints.

FEMALE GENITOURINARY DISORDERS

The response of the premenarchal female to the genitourinary examination depends upon her stage of development. Younger children generally cooperate easily, whereas older children tend to be more private, especially in the early stages of puberty. Putting the child at ease to make the evaluation as atraumatic as possible is crucial. Infants can be examined in a parent's lap. Older girls are more easily evaluated on the examination table. Two positions commonly used to facilitate evaluation of young girls are the frog-leg position and, for girls old enough to cooperate, the knee-chest position. In the frog-leg position, the child is supine on the table with her heels together with her knees and hips flexed (Fig. 287.1). With gentle lateral and outward traction on the labia majora, the hymen and introitus are more easily visualized. The knee-chest position generally affords a better view of the vaginal vault. The child is

instructed to get on her hands and knees, fold her arms, rest on her elbows, and place her head on her arms.

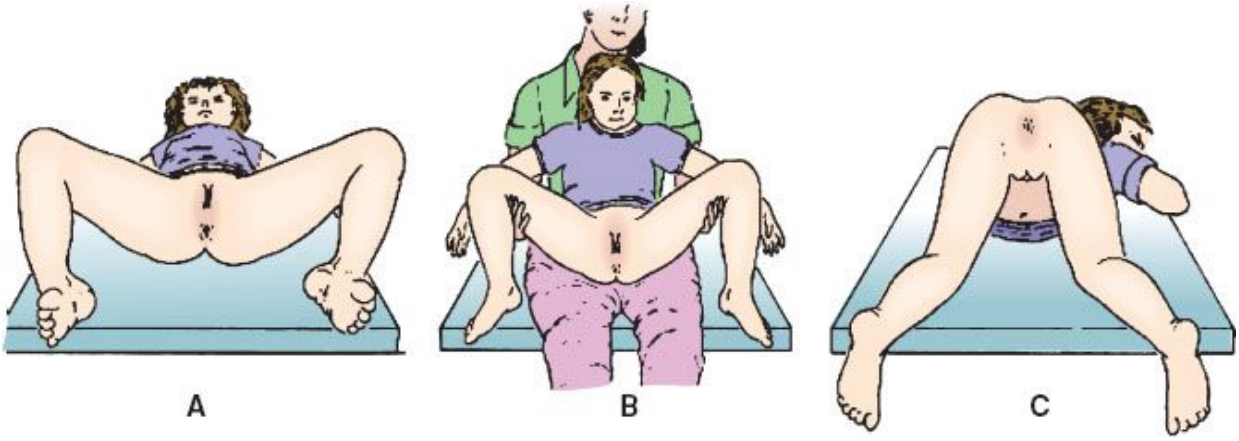

FIGURE 287.1 Positions for genitourinary examination of the female child. **A, B:** Frog-leg position and **(C)** knee-chest position.

A thorough gynecologic examination under procedural sedation or anesthesia may be necessary in young children if vaginal bleeding is present without an obvious source on external examination, if a vaginal foreign body is suspected but not visualized, or if significant trauma is suspected. For most complaints in premenarchal girls, a careful history and physical with a thorough evaluation of the external genitalia and culture of any vaginal discharge is adequate.

When evaluating an adolescent with a genitourinary complaint or abdominal pain, the history must include age of menarche, menstrual history, sexual activity, pregnancies, history of sexually transmitted diseases, and contraception. The adolescent should be interviewed alone. Every postmenarchal girl should have a pregnancy test performed. Virginal females will rarely require bimanual or speculum examinations as pelvic pain in virginal girls generally can be evaluated with transabdominal ultrasonography. Sexually experienced adolescents require a full gynecologic evaluation, given the high rate of sexually transmitted infections in this age group.

PEDIATRIC VULVOVAGINITIS

CLINICAL PRESENTATION

Inflammation of the vulva and vagina is the most common gynecologic complaint in the prepubertal female. Prepubertal patients are predisposed to inflammation due to the absence of labial fat pads and pubic hair for protection and a low estrogen level, leading to a more alkaline vaginal pH. In addition, vaginal proximity to the anus and poor local hygiene increase the risk of inflammation. There generally is no appreciable physiologic vaginal discharge from approximately 1 month of age until the initiation of puberty, although estrogen effects passed from the mother to the female child may last through infancy. Thus, a prepubertal girl with the chief complaint of vaginal discharge warrants a medical evaluation. Patients may also present with pruritus, vaginal redness, soreness, and, rarely, bleeding (1). The postpubertal female may present with a change in vaginal discharge, pruritus, or pain. Frequency and dysuria can be associated symptoms.

The normal prepubertal vaginal flora has not been well studied, and thus the determination of a causative agent can be difficult. Classically, the etiology of vulvovaginitis in pediatrics is usually divided into two groups, specific and nonspecific. Nonspecific vaginitis is usually attributed to poor hygiene, chemical irritation, or tight-fitting clothing. The majority of cases of vulvovaginitis in prepubertal girls are due to nonspecific vaginitis (2). Nonsexually transmitted infections thought to cause vulvovaginitis include Group A β-*hemolytic streptococcus, Staphylococcus aureus,* and *Shigella* (2,3). *Candida albicans* is a rare cause of vulvovaginitis in the prepubertal patient.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis varies depending upon the age and the patient's risk factors. An infant is more likely to have neonatal leukorrhea, diaper dermatitis, impetigo, chemical–mechanical irritation, seborrheic dermatitis, or a genitourinary malformation. Vaginal foreign bodies are generally seen after infancy. Chronic irritation may be secondary to lichen sclerosis, labial adhesions, or a vaginal foreign body. Pinworms that migrate to the vagina can lead

to vulvovaginitis, and should be suspected when nighttime symptoms predominate or there is associated anal pruritis. Pinworms are discussed in greater detail in Chapter 284. In adolescents, urethritis, cervicitis, or pelvic inflammatory disease should be considered.

ED EVALUATION

Visible discharge in a premenarchal patient should be sent for wet mount, cytology, and bacterial cultures. Cultures may be obtained with a moist swab placed in the introitus. The prepubertal hymen and clitoris are extremely sensitive so a small swab should be used, avoiding contact with the hymen, or lidocaine jelly can be applied for analgesia. A culture for chlamydia is usually sent only if other cultures are negative or sexual abuse is suspected. Urine tests are now available for gonorrhea and chlamydia, and can be used to screen for disease. Because diagnosis of a sexually transmitted infection in a prepubertal child is an evidence of sexual abuse, highly specific tests that will be acceptable as evidence in legal proceedings should be obtained before treatment of sexually transmitted infections (4). Appropriate forensic testing is discussed in Chapter 292. Patients who have been sexually active should have a bimanual and speculum pelvic examination and should be tested for sexually transmitted infections.

ED MANAGEMENT

Culture-proven–specific vaginitis can be treated with targeted antimicrobial therapy. Isolation of sexually transmitted organisms in a prepubertal child necessitates child abuse workup and reporting. The treatment of nonspecific vaginitis is focused on proper hygiene (i.e., front-to-back wiping), sitz baths, and avoidance of chemical irritants such as bubble bath and harsh detergents. A diagnosis of candidal vaginitis in a toilet-trained prepubertal patient is unusual, and a workup for diabetes or immunodeficiency should be considered.

DISPOSITION

Patients should follow-up with their pediatrician for culture results and to ensure that symptoms have resolved or with a subspecialist as indicated.

IMPERFORATE HYMEN

CLINICAL PRESENTATION

Imperforate hymen is a rare disorder. In infants and young girls, it is most often discovered incidentally during physical examination. In the neonate, circulating maternal hormones stimulate vaginal mucus secretion. If the imperforate hymen is not recognized at birth, it may present within days to weeks of life when the obstructed vagina becomes distended, resulting in hydrocolpos or mucocolpos. If the distension extends to the uterus, it is referred to as *hydrometrocolpos.* The infant may present with a lower abdominal mass or mass at the introitus, urinary retention secondary to extrinsic obstruction, or constipation. Girls who remain undiagnosed in childhood will present during or after menarche when the vagina fills with blood resulting in hematocolpos or hematometrocolpos. They will have normal pubertal development with primary amenorrhea. The chief complaint may be lower abdominal pain that may or may not be cyclic, back pain, a pelvic mass, constipation, or urinary retention (5).

DIFFERENTIAL DIAGNOSIS

The diagnosis of imperforate hymen is generally made upon examination of the external genitalia. However, other causes of vaginal obstruction must be considered. Transverse vaginal septum, labial adhesions, pelvic mass, agenesis of the vagina, testicular feminization, and Gartner duct cysts should be included as possible diagnoses. Sexual or physical abuse also rarely mimics the presentation of imperforate hymen.

ED EVALUATION

A thorough history and physical should lead to the diagnosis. In infants, imperforate hymen may appear as a whitish bulging membrane. Infants should be evaluated for the complications due to mass effect including evaluation for respiratory distress, inferior vena cava compression, and hydronephrosis. A urinalysis should be performed to assess for concomitant infection. Hematocolpos in adolescents is classically described as a bulging membranous dark blue mass at the introitus. An adolescent with severe pain may require an ultrasound evaluation, as case reports of ruptured hematosalpinx have been documented (5).

ED MANAGEMENT

The treatment for imperforate hymen is surgical incision and resection. The urgency of gynecology consultation or referral is based on patient symptoms.

DISPOSITION

Asymptomatic infants and prepubertal children can be scheduled for elective repair. Patients with complications such as renal insufficiency, respiratory distress, or shock from inferior vena compression require admission to the hospital and emergent intervention. Adolescents with hematocolpos should undergo surgical treatment promptly. In addition, all female siblings should undergo an external examination, as familial occurrences have been reported (6).

URETHRAL PROLAPSE

CLINICAL PRESENTATION

Urethral prolapse is a disorder seen in prepubertal girls and postmenopausal women. In children, the diagnosis is most commonly seen in prepubertal African American girls. The patient presents with painless vaginal bleeding, a vaginal mass, or urinary symptoms of straining or dysuria. The mass is generally swollen, purple or deep red, and doughnut shaped. A central depression representing the

lumen of the urethra may or may not be evident. The area may have evidence of thrombosis and necrosis.

DIFFERENTIAL DIAGNOSIS

Urethral processes that can present similarly are urethral polyps, prolapsed ureteroceles, and rarely urethral carcinomas. Dermatologic causes include condylomata and hemangiomas. Accidental and nonaccidental trauma can cause a hematoma that mimics prolapse. Imperforate hymen and hair tourniquets are other possibilities. An important entity on the differential that must be excluded is botryoid sarcoma, as it requires immediate referral and management.

ED EVALUATION

If the origin of the mass is in question, a catheter can be passed through the mass to verify the diagnosis.

ED MANAGEMENT

Appropriate treatment is debated in the literature with some experts recommending surgical treatment in all cases and others advocating conservative treatment for most patients. In general, if the prolapse is small, without evidence of necrosis and asymptomatic or only mildly symptomatic, sitz baths or warm moist compresses can be recommended. A topical estrogen cream applied twice a day for 2 weeks may aid in resolution. If there is evidence of extreme congestion, necrosis, or if symptoms are significant, a urologic evaluation is indicated for reduction under anesthesia and/or excision (7).

DISPOSITION

The uncomplicated urethral prolapse will generally resolve in 3–6 weeks but may take up to 3 months. Follow-up should be given to all patients to ensure resolution has occurred. Patients with necrosis, severe symptoms or failure to resolve need urologic referral.

VAGINAL FOREIGN BODY

CLINICAL PRESENTATION

The classic presentation of a retained foreign body is vaginal bleeding or blood-stained or foul-smelling vaginal discharge. A prepubertal girl with chronic vaginal discharge should have a thorough workup for vaginal foreign body (8). More commonly reported foreign bodies in prepubertal girls include toilet paper, cloth, and other small items. Adolescents are more likely to present with retained tampons and condoms.

DIFFERENTIAL DIAGNOSIS

The presenting symptoms of a patient with a vaginal foreign body include vaginal bleeding, discharge, and abdominal/pelvic pain. Vulvovaginitis, urethral prolapse, dysfunctional uterine bleeding, labial adhesions, tumor, trauma, and urinary tract infection (UTI) can all present similarly.

ED EVALUATION

The patient should undergo a full genitourinary evaluation. The knee-chest position with a good light source will facilitate the best vaginal examination of a premenarchal patient. The use of an otoscope placed carefully into the hymen may enhance visualization. If a vaginal foreign body is highly likely but not visualized with the foregoing methods, an examination under procedural sedation or anesthesia may be indicated. Postmenarchal patients can undergo a speculum and bimanual examination. An x-ray or ultrasound can be considered, although the objects found are generally not radiopaque.

The relationship between vaginal foreign bodies and sexual abuse has not been well studied or described in the literature. A retrospective case review suggests a possible correlation in some cases; therefore, patients should be questioned about and screened for signs of sexual abuse, especially if the patient has recurrent vaginal foreign bodies (8).

ED MANAGEMENT

If a vaginal foreign body is suspected, a gentle vaginal lavage should be performed. A 50-mL syringe with the plunger removed can be attached to a catheter that is inserted in the introitus. Normal saline poured into the syringe will provide a continuous flow to flush the object out of the vagina. If this procedure is not tolerated or fails to remove the object, a gynecologist can perform vaginoscopy under anesthesia.

DISPOSITION

Most patients are managed as outpatients. Patients with persistent complaints of vaginal discharge or bleeding should be referred to a gynecologist for further evaluation (9).

LABIAL ADHESIONS

Adhesions of the labia minora are a common entity encountered in the pediatric patient. Labial fusion is thought to be due to irritation and inflammation of unestrogenized epithelium with adhesions forming during the healing process. The incidence in prepubertal girls is reported to be less than 5% (10). Most patients are between 1 and 6 years of age. Symptoms may include urinary complaints, recurrent UTIs, vaginitis, or leakage of urine. Labial adhesions may also be noted by parents or on examination by a health care provider. The diagnosis is generally made clinically, with labial tissue with a central line or raphe obstructing the view of the introitus and hymen. The characteristic central thickened line differentiates the diagnosis from congenital malformations.

Appropriate treatment of labial adhesions is controversial. Traditional treatment of labial adhesions was surgical or manual separation of adhesions, or application of topical estrogen cream. Estrogen cream is associated with side effects including vaginal bleeding and breast bud development. Newer literature suggests that betamethasone cream may be more efficacious and associated with fewer side effects than topical estrogen (10). The natural history of labial adhesions is resolution in early puberty when estrogen levels rise. Thus, asymptomatic patients do not require treatment. If the patient is having complications or symptoms, estrogen or

betamethasone cream can be applied sparingly to the adhesions at bedtime for several weeks to months. After separation, zinc oxide or petroleum jelly should be applied at bedtime for an additional 2 weeks. Patients should be followed up closely for failure of separation and recurrence. At that time, manual or surgical separation may be performed.

KEY TESTING

Suspected Disorder	Testing	Consultations/Referrals
Vulvovaginitis	• If discharge present: Wet mount, cytology, culture	• If persistent discharge: Gynecology to rule out foreign body and other serious disease • If child abuse suspected: Child protective services, law enforcement, and child abuse team for further workup and appropriate STI testing
Imperforate hymen	• If severe pain: Ultrasound to assess for complications • If symptoms suggestive: Urinalysis	• Gynecology for surgical repair (urgency based on symptoms)
Urethral prolapse	• Generally none	• If necrotic tissue, severe symptoms or no resolution: Urology
Vaginal foreign body	• Generally none	• If unable to remove or if foreign body suspected, but not visualized: Gynecology • If suspicion of abuse: Child abuse team
Labial adhesions	• If symptoms suggestive: Urinalysis	• If symptomatic and no resolution with topical therapy: Gynecology or Urology

CRITICAL INTERVENTIONS

- Rule out pregnancy in every postmenarchal patient with genitourinary symptoms.
- Evaluate prepubertal pediatric patients diagnosed with a sexually transmitted infection for sexual abuse

- Evaluate infants with hydrocolpos for signs of hydronephrosis, respiratory insufficiency, and compression of the vena cava

Common Pitfalls

- Failure to take a complete sexual history or perform a genitourinary examination because of inaccurate assumptions of low risk
- Failure to recognize that candidal infections in prepubertal patients are unusual and may be associated with diabetes or an immune disorder
- Failure to evaluate pediatric patients with recurrent or chronic vaginitis for a vaginal foreign body or other serious pathology

MALE GENITOURINARY DISORDERS

Any male with abdominal or genitourinary complaints must undergo a complete examination. This section focuses on common testicular and foreskin complaints in pediatric patients.

TESTICULAR TORSION

CLINICAL PRESENTATION

Testicular torsion is a critical diagnosis to make in the ED. Testicular torsion has been reported in all ages from in utero through adulthood, but nearly all cases occur before the age of 25 (11). It is most common during adolescence. Patients classically present with acute onset of severe, unilateral, progressive scrotal pain and swelling. Diffuse scrotal erythema, a horizontal lie, or a high-riding testis may be seen. Patients may also present with atypical features, including pain which is intermittent or bilateral or lower abdominal. It is common for patients to have associated nausea and vomiting. The cremasteric reflex is usually absent; however, the cremasteric reflex is commonly subtle or absent in healthy young boys (12). The presence of a cremasteric reflex is suggestive that torsion is not the correct diagnosis; however, its presence in patients with torsion has been reported (13,14). Patients with an undescended testis have a

higher incidence of torsion and the diagnosis should be considered in males with undescended testicles presenting with abdominal pain or vomiting (15).

Torsion in adolescence is due to improper attachment of the testicle to the tunica vaginalis resulting in the "bell clapper" deformity. The result is a free-hanging testicle, predisposing to twisting of the spermatic cord. The abnormal attachment is usually bilateral.

DIFFERENTIAL DIAGNOSIS

Two other diagnoses which present as atraumatic acute scrotal pain and swelling in pediatric patients are epididymitis and torsion of a testicular appendage. Epididymitis tends to have a more gradual onset of symptoms, an intact cremasteric reflex, and a vertically oriented testis. None of these findings are diagnostic for epididymitis, however. Torsion of a testicular appendage usually presents with less severe symptoms than testicular torsion. With torsion of a testicular appendage, a firm tender nodule can be palpated on the upper pole of the testis and a "blue-dot sign" may be visualized. Delayed diagnoses of testicular torsion frequently result in testicular loss; therefore, testicular torsion must be considered in any patient who presents with scrotal pain. Table 287.1 lists other causes of painful scrotal swelling.

TABLE 287.1
Causes of Scrotal Swelling and Masses

Painful	Generally Painless
Testicular torsion	Inguinal hernia
Torsion of appendix testis	Hydrocele
Epididymitis	Varicocele
Incarcerated hernia	Tumor/metastases
Trauma	Henoch–Schönlein purpura
Edema	

ED EVALUATION

If the patient presents with a history and physical examination most consistent with torsion, immediate urologic evaluation is warranted without further studies. Only if the diagnosis of torsion is uncertain should imaging be performed. Color Doppler ultrasonography has become the imaging modality of choice as it is noninvasive, uses no radiation, and is readily available. Recently published studies have found that color Doppler ultrasound has 94% to 100% sensitivity and 96% to 97.9% specificity for the diagnosis of testicular torsion (15–17).

Additional information that may aid in diagnosis is a urinalysis. If significant pyuria is demonstrated, a diagnosis of epididymitis becomes more likely. However, the presence of pyuria does not rule out testicular torsion.

ED MANAGEMENT

Testicular torsion is a surgical emergency. If the diagnosis is likely, emergent urologic evaluation should be obtained and the patient should undergo scrotal exploration in the operating room. Imaging studies should not delay urologic evaluation or surgical exploration. The survival of the testis is correlated with duration of symptoms. Manual detorsion to increase blood flow to the testis can be attempted as a temporizing measure if the patient cannot be taken to the operating room promptly. Analgesia should be administered prior to the manual detorsion. This maneuver is performed by facing the patient and rotating the involved testicle outward as if one were opening a book: The left testis is rotated clockwise and the right counterclockwise until the symptoms improve. One study demonstrated that the degree of rotation of torsed testes ranged from 180 to 1,080 degrees, with a median of 540 degrees (18). The classically described torsed testis is rotated in the medial direction; however, the same study reported that one-third of the torsed testes were laterally rotated, a fact that should be kept in mind when undertaking detorsion maneuvers (18). Emergent surgical exploration with detorsion and orchiopexy is the definitive treatment.

DISPOSITION

The patient with testicular torsion must undergo surgical exploration of both testes and bilateral orchiopexy.

EPIDIDYMITIS

CLINICAL PRESENTATION

Acute epididymitis is a common cause of acute scrotal pain. The pain of epididymitis is usually gradual in onset. It may be associated with swelling and erythema of the scrotum, fever, vomiting, and urinary symptoms. It is more common in adolescent males; however, the diagnosis is not uncommon in prepubertal boys. The tenderness is generally posterior and lateral to the testis. The cremasteric reflex is usually intact.

DIFFERENTIAL DIAGNOSIS

The main entity that must be distinguished from epididymitis is testicular torsion. Patients with testicular torsion generally have a more acute onset of symptoms, no fever, and fewer urinary complaints.

ED EVALUATION

Urinalysis may demonstrate white blood cells. A urine culture should be sent. If the patient is sexually active, gonorrhea and chlamydia testing should be performed. If the diagnosis of torsion cannot be excluded, color Doppler ultrasonography should be performed to rule out torsion. Increased blood flow to the epididymis will be visualized on ultrasound.

ED MANAGEMENT

The treatment for acute epididymitis depends upon the patient's age. Traditional teaching is to treat all cases of prepubertal epididymitis with antibiotics. Younger children with evidence of an associated UTI on urinalysis should be treated with oral antibiotics to cover common urinary organisms (*Escherichia coli, Klebsiella pneumoniae,*

and *Pseudomonas aeruginosa)* (see Chapter 290). However, recent studies have demonstrated that most prepubertal cases of epididymitis are not associated with UTI (19,20). Therefore, prepubertal children without evidence of UTI or suspicion of a sexually transmitted disease can be treated with supportive care. Although there is little data on young infants with epididymitis, the authors believe that infants younger than 1 month of age should be admitted for inpatient antibiotics and infants between 1 and 3 months of age should be treated with oral antibiotics until cultures are negative (20). Admission should also be considered for patients who appear ill. Most cases of epididymitis in adolescents are due to sexually transmitted infections, and the patient should be empirically treated for *Neisseria gonorrhoeae* and *Chlamydia trachomatis.* Recommended treatment is a single dose of 250 mg of ceftriaxone intramuscularly and 100 mg of doxycycline twice daily for 10 days (4).

DISPOSITION

The patient should be prescribed analgesics, sitz baths, and scrotal elevation, as age permits. Antibiotics should be prescribed as outlined earlier, with a low threshold for admitting young infants. Urologic follow-up should be arranged.

HYDROCELE

CLINICAL PRESENTATION

Hydroceles are common findings in infants and young children. The usual presentation is a painless swollen scrotum that tends to increase in size throughout the day and decrease when supine. The fluid collection may appear after coughing or straining. A simple hydrocele is a fluid collection without a patent processus vaginalis. A communicating hydrocele has a patent processus vaginalis and generally has greater fluctuation in size. Communicating hydroceles may be associated with an indirect inguinal hernia (21).

DIFFERENTIAL DIAGNOSIS

See Table 287.1 for the differential diagnosis of nonpainful scrotal swelling.

ED EVALUATION

Palpation of the scrotum should reveal a normal testis and spermatic cord above the mass. To aid in distinguishing a hydrocele from an inguinal hernia, it should be noted that the spermatic cord above the hydrocele should not feel thickened. A hydrocele is fluid filled and should transilluminate (Fig. 287.2). Testicular tumors pathology may be associated with hydroceles, so if a tumor cannot be ruled out by physical examination, ultrasound evaluation is recommended.

FIGURE 287.2 Hydrocele with transillumination of fluid-filled scrotal sac.

ED MANAGEMENT

If the hydrocele is tense or painful, the patient should undergo a surgical evaluation. If the mass fluctuates in size rapidly or the examination is consistent with a communicating hydrocele, the patient should be referred to a surgeon to rule out an inguinal hernia.

DISPOSITION

A small uncomplicated hydrocele can be managed conservatively, as most resolve spontaneously. Failed resolution at age 2 years warrants a surgical referral for repair (21). Any communicating hydrocele with an associated hernia needs surgical closure. It is recommended that parents be counseled on the signs and symptoms of incarceration.

TESTICULAR TUMORS

CLINICAL PRESENTATION

Testicular tumors present as an abnormally large testis or mass and are generally painless, although there may be associated scrotal heaviness or abdominal pain. Lymphadenopathy may also be present.

DIFFERENTIAL DIAGNOSIS

A testicular or paratesticular mass should be evaluated under the assumption that it is a malignancy. Other entities including hernia, hydrocele, varicocele and in neonates, prenatal testicular torsion, may present as painless scrotal enlargement. Rhabdomyosarcomas, teratomas, epidermoid cysts, and yolk sac tumors present as testicular or paratesticular masses (22).

ED EVALUATION

A full physical evaluation should be performed examining carefully for lymphadenopathy and location of the mass. Testicular and paratesticular masses should be evaluated by ultrasound. β-Human chorionic gonadotropin (β-HCG) is rarely elevated in prepubertal testicular tumors, but a urine or serum β-HCG can be checked (22). Alpha-fetoprotein (AFP), is elevated in yolk sac tumors; however, AFP levels in healthy infants may be elevated (22).

ED MANAGEMENT AND DISPOSITION

A pediatric surgeon or urologist should be consulted for further workup and management. Patients should be admitted or very close follow-up must be arranged.

INGUINAL HERNIA

Approximately 15 in 1,000 births result in an abdominal hernia, with a higher incidence in premature infants. Inguinal hernias are more common in males, with bimodal peaks before 1 year of age and then again after age 40. An indirect inguinal hernia occurs when the processus vaginalis does not obliterate in infancy and abdominal contents invaginate through this patent sac. These hernias are more common on the right side. Entrapment of mesentery, bowel, intraperitoneal organs, and the hernial sac can occur and are more common with small hernias. If the contents of the hernia can be returned to their anatomic position, the hernia is termed *reducible;* if it remains entrapped, it is termed *incarcerated* or *irreducible.* Hernias that remain incarcerated can result in strangulation, with resultant bowel necrosis.

CLINICAL PRESENTATION

Patients with incarcerated hernias may present with pain, edema extending to the scrotum, nausea, vomiting and low-grade fever. Physical examination may reveal bowel sounds in the scrotal sac. If the inguinal mass can be palpated separately from the testes, then it is possible to diagnose an inguinal hernia clinically. A strangulated hernia can present as a tense, blue mass in the scrotum.

ED MANAGEMENT AND DISPOSITION

The patient should be placed in the Trendelenburg position with an ice pack placed on the groin, as tolerated, to reduce swelling; pain medication or sedation may be necessary before reduction. Slow gentle pressure should be applied to reduce the hernia. The parent or child may assist in applying. If the hernia cannot be reduced or strangulation is suspected, the patient should receive fluid resuscitation and broad spectrum parenteral antibiotics, and surgical consultation should be obtained (21).

Patients with reducible hernias should be referred for outpatient surgical repair.

PHIMOSIS

Phimosis occurs when the foreskin cannot be retracted over the glans. When caused by normal physiologic adhesions, it is called *primary phimosis.* Phimosis is normal in infants and young children, with resolution generally by 6 years of life. Secondary phimosis may occur owing to scarring of the foreskin after inadequate circumcision or due to irritation or infection. Patients generally are asymptomatic. However, in some patients, the constriction causes voiding difficulty, UTI, and local infection of the foreskin and glans.

Physical examination establishes the diagnosis. If symptoms of a UTI are present, urinalysis and urine culture are warranted. Renal function tests and a bedside or formal renal ultrasound should be performed if significant urinary obstruction is suspected.

No treatment is needed for asymptomatic patients younger than 6 years of age. Symptomatic phimosis can be treated with topical steroids, or if conservative treatment fails, with circumcision. Steroid treatment has been shown to be effective in 75% to 88% of boys (23–25). Betamethasone 0.05% or other steroid cream applied to the stretched foreskin twice daily for 1 month is commonly recommended. Symptomatic patients and older boys should have urologic follow-up.

PARAPHIMOSIS

Paraphimosis is a condition seen in uncircumcised males when the foreskin is retracted over the glans for a prolonged period. This leads to edema and venous congestion of the foreskin and glans and eventually impairs blood flow to the glans. The patient presents with increasing swelling and pain. Paraphimosis can occasionally occur in males with a history of circumcision if insufficient foreskin tissue was removed. The diagnosis is made clinically, systematically ruling out hair tourniquet syndrome.

Treatment requires reduction of the foreskin to restore its normal position over the glans. This is best accomplished with effective pain control. Options include oral or parenteral pain medication, procedural sedation, topical anesthetic creams, or a penile block. Controversy exists as to methods of reduction of the foreskin. Reduction is facilitated by first reducing swelling by manual compression, use of sugar-soaked solutions to the area, or aspiration of the fluid in the edematous tissue (24,26). The physician should then place both thumbs on the glans with the index and middle fingers on the distal end of the foreskin. Simultaneous persistent pressure is applied to the glans with the thumbs and to the rolled edge of the foreskin with the fingers so as to return the foreskin to its proper position. If the foreskin cannot be reduced, emergent urologic consultation is necessary. If phimosis is successfully reduced in the ED, urologic follow-up is recommended for possible circumcision.

BALANITIS AND BALANOPOSTHITIS

A break in the foreskin caused by local trauma or poor hygiene can lead to posthitis. Extension of the cellulitis or inflammation to the glans is referred to as *balanoposthitis*. The patient presents with swelling, erythema, and penile pain. Purulent discharge may be present. A culture of any discharge may be sent for identification and proper antibiotic treatment.

The responsible organisms are typically skin flora (i.e., *Staphylococcus* and *Streptococcus*). Treatment includes sitz baths and topical antibiotics. In more severe cases, cephalexin (25 to 50 mg/kg/d divided three times daily for 7 days) can be added (24). Follow-up is recommended, as treatment failures, repeated episodes,

and scarring can lead to phimosis. Patients not in diapers with *candidal* balanitis or balanoposthitis should be evaluated for diabetes mellitus. Patients with swelling severe enough to cause obstruction or concern for a more invasive infection should be admitted for urologic evaluation and intravenous antibiotics.

KEY TESTING

Suspected Disorder	Testing	Consultations/ Referrals
Testicular torsion	• None if diagnosis is likely • Ultrasound if signs/ symptoms make torsion possible but less likely	• Emergent urologic consult
Epididymitis	• Urinalysis and culture • Sexually transmitted infection testing for sexually active males • Ultrasound to confirm diagnosis	• Outpatient urologic follow-up
Hydrocele	• Ultrasound if testis not adequately palpated	• Outpatient pediatric surgery follow-up if persistent past age 2 years or if associated with a hernia
Inguinal hernia	• Generally none	• Emergent surgical consult if strangulated or if unable to reduce incarcerated hernia • Outpatient pediatric surgery follow-up for reducible hernias
Phimosis	• Generally none	• Outpatient urology follow-up in older children or if symptomatic
Paraphimosis	• Generally none	• Consider outpatient urologic follow-up
Balanitis and balanoposthitis	• Consider culture if discharge present • Glucose level if Candidal infection present in toilet-trained child	• Outpatient urologic follow-up if recurrent

CRITICAL INTERVENTIONS

- In patients with suspected testicular torsion, obtain immediate urologic evaluation without waiting for ultrasound confirmation of diagnosis.

- Order an ultrasound in patients with hydroceles if adequate palpation of the testis is not possible as hydroceles can be associated with testicular tumors.
- Obtain an emergent urologic consultation for patients with paraphimosis that cannot be reduced.

Common Pitfalls

- Failure to perform a complete abdominal and GU examination on all males with a complaint of abdominal pain or vomiting
- Delay of urologic consultation in patients with suspected testicular torsion
- Failure to consider testicular torsion in patients with abdominal pain or vomiting and an undescended testicle

CHAPTER 288

Urinary Tract Infections in Children

Nazreen Jamal and Kathleen Brown

CLINICAL PRESENTATION

Urinary tract infections (UTIs) are the most common serious bacterial infection in infants and young children. However, the diagnosis can be challenging as the clinical presentation and prevalence of UTI varies with age. Children under 2 years of age usually present with fever alone or nonspecific symptoms such as vomiting, diarrhea, failure to thrive, irritability, and jaundice. Preschool children may present with more specific symptoms such as suprapubic pain, urgency, dysuria, and frequency, though some children in this age group may also present with only nonspecific symptoms. Enuresis in a previously continent child may be an indicator of possible infection. In the school-age child with a UTI, symptoms associated with the urinary tract are usually present. Fever may or may not be present, and although it suggests upper tract disease, fever can be present in patients with cystitis and may be absent in a patient with significant renal involvement. Though parental report of malodorous urine is associated with an increased likelihood of UTI, the sensitivity and specificity is not sufficient to be diagnostic (1).

Given the variability in presentation, an understanding of prevalence among subgroups of children can help to better inform the decision to test children for UTI. A meta-analysis showed an overall prevalence of 7% in febrile infants and 7.8% among older

children with urinary complaints. The rates varied significantly, however, based on the child's age, race, gender, and circumcision status. The highest prevalence of UTI was found in febrile uncircumcised males <3 months of age and febrile females <12 months of age (2).

DIFFERENTIAL DIAGNOSIS

In infants, UTI should be included in the differential diagnosis of fever, irritability, gastroenteritis, failure to thrive, and sepsis. When preschool-age and older children present with urgency, dysuria, or frequency, the differential diagnosis for this complex of symptoms should include urethritis, pinworms, vaginitis, and child abuse. Physical examination of the genitalia is necessary to assess for the presence of these problems. Children with constipation are at increased risk of UTIs, and the diagnosis should also be considered in these patients. In the adolescent patient, the presence of sexually transmitted diseases needs to be considered. In addition, patients with group A *Streptococcus* infection, Kawasaki disease, and appendicitis may also present with fever, abdominal pain, and pyuria. A complete history and physical examination can help in the differentiation of these illnesses.

ED EVALUATION

The diagnosis of UTI in children requires the presence of pyuria or bacteriuria on a urinalysis (UA) *and* at least 50,000 colony-forming units per mL of a known uropathogen from a urine sample obtained by urine catheterization or suprapubic aspiration (SPA) (3). Therefore, both UA and urine culture should be obtained when considering a diagnosis of UTI in children. In addition, the presence and risk for short-term complications such as sepsis or meningitis needs to be evaluated, especially in the young infant. The overall risk of bacteremia is highest in children less than 6 months of age (8%), and meningitis in children less than 2 months of age (4–7). As with any pediatric patient, the need for supportive therapy,

including intravenous (IV) hydration, and laboratory studies (to assess renal function) should be considered as clinically indicated.

Who Should Be Screened for UTI?

In 2011, the American Academy of Pediatrics (AAP) issued a revision of its clinical practice guidelines for the diagnosis and management of first time UTIs in children 2 to 24 months. While the previous recommendation advocated for UTI screening of all girls and uncircumcised males less than 2 years with unexplained fever, the most recent guidelines recommend screening based on risk factor stratification (3). The risk factors include (1) child's gender, (2) circumcision status in males, (3) patient race, (4) duration of fever greater than 24 hours, (5) height of fever greater than 39°C, and (6) absence of an alternative source of fever. UTI screening is recommended for children who are not at low risk defined as either $<1\%$ or $<2\%$, depending on clinical scenario and number of risk factors a given patient possesses (Table 288.1). These guidelines do not apply to children with a previous history of UTI, for which the threshold for screening should be lower, nor for ill-appearing children who are determined to require immediate empiric antibiotics, for which urine specimens should be obtained prior to antibiotic administration.

TABLE 288.1
Prevalence of UTI in Children Varies Based on Age, Gender, Race, and Circumcision Status

Febrile Males <3 mos	
Circumcised	2.4% (CI: 1.4–3.5)
Uncircumcised	20.1% (CI: 16.8–23.4)
Febrile Females	
0–3 mos	7.5% (CI: 5.1–10)
3–6 mos	5.7% (CI: 2.3–9.4)
6–12 mos	8.3% (CI: 3.9–12.7)
12–24 mos	2.1% (CI: 1.2–3.6)
Race	
White	8% (CI: 5.1–11)
African American	4.7% (CI: 2.1–7.3)
<19 yrs with urinary symptoms	7.8% (CI: 6.6–8.9)

Modified from Shaikh N, Morone NE, Bost JE, et al. Prevalence of urinary tract infection in childhood: A meta-analysis. *Pediatr Infect Dis J*. 2008;27(4):302–308.

Notably, the absence of another source for fever is included as a risk factor for UTI, but the presence of a diagnosis of a viral infection does not preclude a concomitant UTI. Two large, prospective, multicenter studies evaluated the risk of serious bacterial infection in febrile infants ≤60 days of age with proven viral infections with influenza and respiratory syncytial virus (RSV). Krief et al. (8) noted febrile infants with influenza had a significantly lower (but not absent) rate of UTI (2.4%) than influenza-negative infants (10.8%). Similarly, in a study comparing rates of serious bacterial infections in febrile infants with and without RSV, infants with RSV were found to have a significantly lower rate of UTI (5.4%) compared to those without RSV (10.1%). While rates of UTI may be lower in young febrile infants with viral infections, the presence of a concomitant UTI must still be considered (9).

How Should Specimens Be Collected?

A clean catch sample (obtained with the help of an adult) is an acceptable means of obtaining a specimen for culture and screening tests in children who are continent of urine. In these children, cleaning of the perineum has been shown to significantly decrease

the rate of contaminated specimens (10). However, in children who are not yet continent of urine other methods of collection must be utilized. The recent AAP guidelines offer two options for urine testing in children less than 24 months of age. The first is to obtain a UA and urine culture by urethral catheterization or SPA. The second is to collect a screening UA through the "most convenient means," followed by a UA and urine culture through catheterization or SPA if the initial UA is suggestive of a UTI (3).

Urine obtained by SPA or transurethral catheterization is unlikely to be contaminated and therefore is the preferred specimen for documenting UTI. Both techniques have limited risks but require some skill and experience, particularly in small infants, girls, and uncircumcised boys. Many physicians and parents perceive these procedures as unacceptably invasive and prefer to collect urine specimens from a bag affixed to the perineum. If a UA collected in this manner is negative, further testing can be avoided. However, positive results require confirmation since bagged specimens are likely to yield a high rate of false-positive results no matter how well the perineum is cleaned.

Both options are acceptable in situations where immediate empiric antibiotic therapy is not clinically indicated. However, if immediate antibiotic treatment is clinically indicated, urine should be obtained by SPA or catheterization prior to administration of antimicrobials, as the opportunity to confirm the presence of a UTI may otherwise be lost.

KEY TESTING

- UA and urine culture
  - Catheterized specimens recommended for patients who are not yet continent of urine
  - Bag specimens can be used for screening UA, but should be followed with catheterized specimens for repeat UA and urine culture if positive
- Blood cultures and lumbar puncture in febrile infants <4 weeks of age and when otherwise clinically indicated

• Renal function tests only as clinically indicated

ED MANAGEMENT

The major considerations in managing a child with a possible UTI include assessing for need for hydration, antibiotic therapy, and inpatient admission.

Who Should Be Treated in the ED?

The gold standard for diagnosis of UTI requires both UA and urine culture results. However, screening tests are often relied upon to make treatment decisions in the emergency department because delayed initiation of antibiotic therapy has been associated with increased severity of infection (11,12). A UA that includes microscopy with a hemocytometer is more sensitive and specific than a urine dipstick, however is not always available. A UA positive for leukocyte esterase, nitrite, or microscopy positive for white blood cells or bacteria is considered a positive UA, and is suggestive, but not diagnostic of UTI. The diagnosis of UTI is highly unlikely ($<0.3\%$) when the UA is negative. Initiation of antibiotics is recommended when the UA is positive, with subsequent discontinuation of antibiotics if the urine culture is negative (3).

Who Should Receive Parenteral Antibiotics?

In the past, it has been recommended that all infants with a UTI be hospitalized for IV antibiotic therapy. More recent studies indicate that it may be safe to consider outpatient therapy for otherwise healthy infants older than 1 month of age with a presumptive UTI who do not appear toxic, are tolerating oral fluids, and are likely to be compliant with oral antibiotics (13,14). Initiating therapy with oral or parenteral therapy is equally efficacious under these conditions (Table 288.2) (3). Patients not meeting criteria for admission for IV antibiotics can be safely treated as outpatients with appropriate follow-up.

TABLE 288.2
Indications for IV Antibiotics

Toxic appearance
Age <4 wks
Unable to tolerate oral antibiotics
Require ongoing hydration
Require IV pain control

Which Antibiotic Should Be Used?

Antibiotic selection should be tailored to the age of the child being treated and guided by local antimicrobial sensitivity. A list of antibiotics commonly used in the treatment of UTI is listed in Table 288.3. Knowledge of regional and local resistance patterns is essential to initiating appropriate antibiotics for oral therapy. The antibiotic can later be adjusted once the sensitivity of the isolated uropathogen is available (3). Recent data demonstrate that resistance to many drugs traditionally used to treat UTIs in children is unacceptably high and rising. In a national survey, *Escherichia coli,* the most commonly isolated uropathogen, had the highest resistance rates to ampicillin (45%) and trimethoprim-sulfamethoxazole (24%) (15). First-generation cephalosporins and nitrofurantoin were found to be narrow spectrum drugs with low resistance rates. However, drugs such as nitrofurantoin, which are excreted in the urine but do not reach therapeutic concentrations in the bloodstream, should be avoided in the treatment of febrile UTIs in infants (Table 288.3) as they may be insufficient to treat pyelonephritis or suspected urosepsis (3).

TABLE 288.3
Empiric Antimicrobial Agents for Treatment of UTI

Parenteral	Oral
Ceftriaxone	Amoxicillin-clavulanate:
75 mg/kg, every 24 hrs	20–40 mg/kg/d in 3 doses
Cefotaxime	Trimethoprim-sulfamethoxazole:
150 mg/kg/d, divided every 6–8 hrs	6–12 mg/kg trimethoprim and 30–60 mg/kg sulfamethoxazole per day in 2 doses
Ceftazidime	Cefixime
100–150 mg/kg/d, divided every 8 hrs	8 mg/kg/d in 1 dose
Gentamicin	Cefprozil
7.5 mg/kg/d, divided every 8 hrs	30 mg/kg/d in 2 doses
Tobramycin	Cefuroxime axetil
5 mg/kg/d, divided every 8 hrs	20–30 mg/kg/d in 2 doses
Piperacillin	Cephalexin
300 mg/kg/d, divided every 6–8 hrs	50–100 mg/kg/d in 4 doses

Modified from Subcommittee on Urinary Tract Infection, Steering Committee on Quality Improvement and Management, Roberts KB. Urinary tract infection: Clinical practice guideline for the diagnosis and management of the initial UTI in febrile infants and children 2 to 24 months. *Pediatrics*. 2011;128(3):595–610.

How Long Should Patients Be Treated?

Recommendations on the duration of therapy vary. Because short-course and single-dose therapies have been successful with women, short-course regimens may be acceptable for uncomplicated cystitis in adolescent girls. For febrile children 2 to 24 months of age, 1- to 3-day courses of antibiotics have been shown to be inferior to longer courses; the current recommendation is to treat for a total of 7 to 14 days (3,16). Studies of short-course therapy in children have yielded conflicting results and it is often difficult to differentiate uncomplicated cystitis from pyelonephritis in younger children, therefore, most experts still recommend a 7- to 10-day course of antibiotics in prepubertal children with cystitis and up to 14 days when pyelonephritis is suspected. Follow-up within 48 hours should be arranged to ensure children are demonstrating an adequate response to therapy.

CRITICAL INTERVENTIONS

- Screen febrile infants with a high likelihood of UTI based on presence of risk factors
- UA can be obtained by catheterization, suprapubic aspiration, or by urine bag attached to the perineum when screening for UTI. However, the latter requires a second urine sample if screening is positive.
- A positive UA should *always* be confirmed by a urine culture sent from a urine sample obtained by *catheterization or SPA only*
- Assess all children with suspected UTI for the presence of dehydration, sepsis, and renal failure
- Treat children with suspected UTI or pyelonephritis promptly with antibiotics known to have a low rate of resistance in your locality
- Make sure caregivers of young children understand the importance of follow-up and the possible need for repeat urine culture and anatomic evaluation

DISPOSITION

Most patients older than 1 month of age can be safely managed as outpatients. In any patient managed as an outpatient, an initial dose of antibiotic should be given in the ED either orally or parentally. Though early initiation of appropriate antibiotic does not necessarily protect against renal scarring, prompt diagnosis and treatment of UTI continues to be recommended to reduce the risk of renal involvement (12,17). Previously, strategies to prevent renal scarring in children relied upon the use of imaging after UTI to detect abnormalities of the genitourinary tract that would require additional evaluation. However, due to the lack of evidence supporting routine screening with voiding cystourethrograms (VCUG) on all children with febrile UTIs, the AAP recommendations have since been revised. The new guidelines continue to recommend that all children 2 months to 2 years of age with a febrile UTI undergo a renal and bladder ultrasound (US). The US need only be performed during the acute illness *if* the patient is not responding appropriately to antibiotics. A VCUG, however, should be performed

only if abnormalities are noted on the screening US (3). Although these studies would not be performed in the ED, the emergency physician should be cognizant of the latest recommendations to provide appropriate anticipatory guidance and follow-up instructions to families.

Common Pitfalls

- Failure to consider UTI as a source of fever in otherwise asymptomatic children leads to missed or incorrect diagnoses. Viral infections do not preclude UTI as the source of fever in the young child.
- Failure to obtain a urine culture by catheterization or SPA to confirm positive screening UAs may lead to inaccuracies in diagnosis and uropathogen isolation.
- Failure to recognize local antibiotic resistance patterns may lead to ineffective treatment.
- Failure to ensure appropriate follow-up can fail to detect children with treatment failure or progression of disease.

CHAPTER 289

Psychosocial and Behavioral Emergencies

Cynthia J. Mollen

Mental health disorders in children have become a significant health problem. It is estimated that one of every five children in the United States meets criteria for a mental health disorder with at least some impairment expected over their lifetime (1). These patients frequently present to the emergency department (ED) (2,3). Though the mental health needs of children are quite large, there are many barriers to accessing mental health services for pediatric patients, such as lack of insurance, insufficient numbers of specialists who care for children with mental health problems, and the stigma accompanying mental health disorders (4,5). In addition, barriers specific to care in the ED setting include lack of knowledge about pediatric psychiatric illness, limited time, the use of many ED resources, and frequent revisits, contributing to overcrowding (6,7).

CLINICAL PRESENTATION

Depression and Suicide

Depression-related suicidal ideation is the leading serious psychiatric cause for an ED visit. The prevalence of depression increases through adolescence, with 1-year prevalence estimates of 3% to 8% and a lifetime prevalence of approximately 20% (8,9). Depression can be difficult to diagnose because of fluctuating symptoms or vague presenting complaints (8).

Common symptoms of depression include: Sadness, irritability, boredom, mood swings, anxiety, school refusal, declining grades, and substance abuse. While suicide and depression are closely associated there are multiple suicide-specific risk factors, including a family history of suicide, a personal history of a suicide attempt, and poor school attendance (5,10,11).

Anxiety, Obsessive–Compulsive Disorder, and Posttraumatic Stress Disorder

Anxiety disorders, such as panic disorder, separation anxiety, phobias, posttraumatic stress, or obsessive–compulsive disorder, are the most prevalent type of mental health disease in children and adolescents (12). Anxiety in children is often manifested by nonspecific physical complaints. Therefore, an extremely thorough history to separate organic disease from anxiety-related disorders is vital.

Neurobehavioral

There are numerous visits to the ED by children with known neurobehavioral disorders such as attention deficit hyperactivity disorder (ADHD), often because of worsening symptoms or medication-related problems, such as adverse reactions or abuse of medications. For example, use of stimulant medications for ADHD can lead to loss of appetite and weight loss. Medications can be abused for the purpose of weight loss or for recreational purposes (13). Furthermore, children with ADHD or other behavioral disorders may present to the ED for routine emergency complaints; it is important to consider how their underlying disorder(s) or baseline medications may complicate evaluation and medical management with particular attention toward sedation and prescription medications.

Differential Diagnosis

When considering the potential etiologies of a pediatric mental health emergency, emergency physicians must recognize several organic medical disorders may present as acute behavioral disturbances. Alternative medical diagnoses to consider include many disease categories considered in the evaluation of adult psychiatric patients including intracranial lesion or injury, acute drug intoxication or withdrawal, CNS infection, endocrinopathies (i.e., hyper- or hypothyroidism). Among children additional etiologies to consider should include abuse or neglect, metabolic disturbance, and undiagnosed seizure disorder.

When differentiating between organic and psychiatric etiologies of psychosis, consider organic etiologies in patients with the following: (1) New or sudden onset of symptoms with no previous psychiatric history, (2) altered level of consciousness, or (3) abnormal vital signs, neurologic changes, or physical examination findings.

ED Evaluation

When dealing with a pediatric mental health problem the history is perhaps the most critical aspect of the ED encounter. Children, especially younger ones, are usually unable to provide a clear history of past and current problems, so ED physicians must rely on information from numerous other sources, including parents, siblings, relatives, teachers, and other health care providers.

A standard medical history should be performed, and additional questions should explore the circumstances for the ED visit including escalating behavioral problems, threats to self or others, changes in affect, and school performance can be important indicators of severe disease. When the patient is old enough to engage in the history (often as young as 4 or 5 years old), questions should be directed at the patient, with additional questions to the caretaker. It can often be useful to interview the caretaker alone as well. A detailed medication and substance use history is also important, including questions about compliance and side effects, and a complete physical examination is necessary as well.

Adolescents with mental health complaints require a thorough psychosocial assessment by qualified mental health professionals or physicians and should be interviewed with extreme attention to confidentiality. Several structured interview approaches have been widely accepted as templates for gathering information on all aspects of teenage life. Generally these structured interviews progress slowly from less sensitive topics to more sensitive ones (Table 289.1) (14,15). Prior to the start of the psychosocial interview, it is imperative to clarify with patients when confidentiality will be maintained and when it may be needed to be breached (such as if the patient reveals the possibility of harm to themselves or others or in circumstances where mandatory reporters must alert authorities about potential abuse) (16). The confidential interview is critical as it may be the only mechanism for identifying risk factors linked to depression, including substance abuse, sexual orientation and behavioral issues, and the presence of firearms in the home. In addition, this provides the best setting to screen for suicide, which should be included in all assessments of adolescent patients (5,10–12,17). One approach recommend by the American Academy of Pediatrics (AAP) is to ask a general question such as, "Have you ever thought about killing yourself or wished you were dead," followed by, "Have you ever done anything on purpose to hurt or kill yourself?" These questions should be toward the end of questions about depressive symptoms (10).

Suicidality and depression	Sexuality
	Safety

The ED evaluation of mental health complaints must be tailored to the specific problem. In many instances, no laboratory or radiologic imaging will be required, such as in cases of a patient with a known history of depression and an exacerbation of suicidal thoughts but no actions. In contrast, any patient with a change in mental status not accounted for by psychiatric disease, with generalized medical or traumatic complaints, or in whom the diagnosis is uncertain should undergo a focused diagnostic medical evaluation for medically indicated. Selective testing for well-considered medical disorders are much more likely to yield meaningful results than batteries of tests blindly ordered for screening purposes (18).

KEY TESTING

Testing should be guided by the patient's signs and symptoms. Diagnostic tests to consider in appropriate cases may include some or all of the following: Complete blood count; serum electrolytes, blood urea nitrogen, creatinine, and glucose; liver function tests; ammonia level; urine pregnancy test (bHCG) in females; electrocardiogram; chest x-ray; head computed tomography (CT); lumbar puncture; and thyroid function tests. Other tests, such as antinuclear antibody (ANA), are ordered less frequently. Diagnostic testing for patients with mental health complaints should be selective and thoughtful. Not all patients require laboratory evaluation and tests should not be ordered indiscriminately or for screening purposes. Serum and urine toxicologic screens are

frequently a focus of ED testing for mental health patients. Specific agents included on available laboratory screens tend to differ from hospital to hospital, and ED physicians must be aware of local variations. Although many inpatient psychiatric facilities require such testing prior to admission, toxicology testing should never be forced upon a patient simply because of a parent's or caretaker's request (17). Rather, there should be a definite medical or psychiatric indication for testing (16).

ED Management

The ED management of pediatric mental health disorders varies according to the disorder. The ED physician's role is one of advocacy and usually involves evaluating for organic disease and determining the need for consultation and potential transfer to a specialized mental health facility. In the setting of an acute psychiatric or behavioral crisis, the need to provide for safety of patients and caregivers and to limit disruption to the care of patients is paramount. Although rarely necessary in children, physical and chemical restraints are important elements of safety and often complement each other. Many patients can be calmed through techniques other than physical or chemical restraints, such as decreasing stimulation, providing one-to-one support, using relaxation activities, and involving family members. If restraints become necessary, appropriate policies and procedures must be followed.

The AAP statement on the use of physical restraints calls for documentation of the reasons for use of restraint, specific orders (verbal or written) with an attempt to define time limits of use, assessment that restraints are being used properly (not causing physical harm to patient) with close monitoring, and for possible release from restraints when the acute crisis has abated and safety can be assured (19). The practice of patient restraint is carefully regulated by the Joint Commission of Healthcare Organizations. It emphasizes that physical and chemical restraints must be used as a last resort when other methods to control the patient have failed.

The Joint Commission also requires that each health care facility have a written policy and procedure in place to ensure appropriate use (20).

Chemical restraint may be needed when a patient continues to be agitated while in physical restraints or, in specific cases, as an option prior to physical restraint. In children, commonly used medications for chemical restraint are benzodiazepines and butyrophenones. These drugs are useful in the control of agitated behavior and have a long duration of action. An alternative sedative is diphenhydramine; however, this should be used with caution because it may cause paradoxical excitement.

CRITICAL INTERVENTIONS

- Perform a thorough medical evaluation first to exclude organic causes for symptoms
- Consider depression in children who present with a change in their behavior
- Assess thoroughly for suicidal thoughts, intent, and plan
- Question adolescents with an emphasis on privacy and confidentiality
- Document the indication for restraints, if they are needed, and frequently reassess this need

Disposition

A team approach to the ED evaluation of pediatric mental health disorders is considered optimal. Physicians, nurses, social workers, child life personnel, ED technicians, security personnel, and mental health consultants all play a role in establishing an effective evaluation, treatment plan, and safe disposition. However, it is recognized that many EDs will not have this comprehensive set of resources. EDs lacking specific mental health resources should have established referral patterns and a mechanism for transfer or hospitalization. Other potential resources for families with children with mental health needs include primary care physicians, the

school system, clergy, support groups, and community-based mental health centers.

In patients who are considered to be at immediate risk for suicide, one-to-one observation by an ED staff member must be initiated and maintained throughout the ED stay. All pediatric patients who are actively suicidal should have consultation with a mental health provider. If hospitalization is recommended by either the emergency physician or mental health consultant, it is preferred that the parent or patient consent to admission. In cases where the patient is a mature minor and refuses hospitalization, an involuntary commitment order may need to be applied if the patient is considered to be at risk for harm to self or others. An emergency physician or mental health physician is authorized to apply such a commitment. The specifics of involuntary commitments vary from state to state and it is incumbent upon providers to be aware of the state laws governing the commitment of minors for mental health treatment.

Depressed patients who are not actively suicidal and not considered high risk, with no access to lethal methods and a supervising adult who can closely monitor their behavior may be discharged with urgent outpatient follow-up (21). Emergency physicians should take extra precautions to ensure follow-up is prearranged at the time the patient leaves the ED and that an alternative plan is in place if follow-up fails (i.e., primary care visit, return to the ED).

Common Pitfalls

- Failure to aggressively explore nonspecific complaints in a child or adolescent who do not seem to have an organic basis for the possibility of depression/suicide. Depression often masquerades as nonspecific somatic complaints and many depressed and suicidal patients have visited a physician shortly before attempting suicide.
- Failing to enquire about the presence of firearms in the home or access to firearms in general as part of disposition planning. The

presence of firearms in the home is considered a highly lethal risk factor for completion of suicide.

- Failure to detect medical conditions with presenting symptoms that mimic psychiatric disorders. Metabolic, infectious, and toxicologic problems related to acute mental status changes should be assumed to have an organic etiology, particularly, in the case of a first episode or in a younger patient with no known psychiatric or behavioral disorder.

CHAPTER 290

Child Abuse: Physical, Sexual, and Neglect

Dana M. Kaplan

Child maltreatment refers to the abuse and neglect of a child under the age of 18 by a parent or another caregiver, resulting in harm or risk of harm to the child. In 2011, U.S. state and local child protective services (CPS) received an estimated 3.7 million referrals, 681,000 of which were founded (1). Seventy-nine percent were victims of neglect, 18% were victims of physical abuse, 9% were victims of sexual abuse, and 10% were victims of other types of maltreatment (1).

The emergency department (ED) is a common setting for victims of child maltreatment to present. Abused or neglected children may be brought to the ED for common pediatric conditions or in critical condition as a result of abusive injuries and/or neglectful behavior. The history provided by the caregiver and/or patient remains the most important diagnostic tool when assessing for abuse and neglect.

All medical professionals in the United States are mandated reporters of suspected child abuse, with specific requirements in each state. Medical professionals are not required to prove abuse or neglect; law enforcement and CPS will determine if a suspicion is substantiated. No penalty may be brought against medical professionals reporting in good faith; however, serious penalty may result for failure to report suspected child abuse. It is therefore crucial to have a low threshold for reporting concerning injuries to the appropriate authorities.

PHYSICAL ABUSE AND NEGLECT

Child maltreatment can be defined by two categories: (1) An action (commission) or (2) a lack of action (omission) resulting in actual harm or possible harm to a child. Acts of commission include words or actions that harm the child physically, sexually, or emotionally. Acts of omission refer to child neglect. Neglect encompasses the failure to protect a child from harm and/or a failure to provide for a child's basic physical, emotional, or educational needs (2). This section discusses primarily child physical abuse.

Child physical abuse affects children of all ages, genders, ethnicities, and socioeconomic groups. Although the risk of physical abuse increases with age, fatal abuse and serious abusive injuries are more common among children and infants younger than 2 years (3).

CLINICAL PRESENTATION

Physically abused children may present to the ED in virtually any condition ranging from benign and well appearing to critical depending on the type and severity of injury. For some children, an injury is the presenting complaint; for others, an injury, abuse, or neglect is uncovered only during the course of the ED evaluation. What these patients share almost universally are vague, and at time evasive, histories. Emergency physicians must perform careful focused interviews to uncover how an injury may have occurred and to fill in vital missing details to determine if there are any other comorbidities associated with the injury. When evaluating a patient for an injury, the physician must consider the comorbidity of neglect. For example, an infant evaluated for an unexplained leg fracture may also be diagnosed with failure to thrive (3). It is important to appreciate that injuries have many causes and abuse is but one of them; assumptions of guilt should be avoided.

DIFFERENTIAL DIAGNOSIS

To establish whether an injury is accidental or inflicted relies on a plausible history of trauma that is consistent with the child's

developmental status (3). The differential for an injury must include medical conditions that mimic inflicted injuries. Some cutaneous conditions mistaken for abuse include dermal melanocytosis, vascular cutaneous markings (e.g., flame nevi), bullous impetigo, contact dermatitis, chemical burns. When evaluating for fractures, some conditions mistaken for abusive injuries include physiologic subperiosteal new bone formation, nutritional deficiencies, Caffey disease, leukemia, osteomyelitis, and osteogenesis imperfecta (4).

ED EVALUATION

It is important to maintain a neutral professional manner throughout the evaluation with parents and avoid being accusatory or judgmental. Obtaining and documenting a chronologic timeline of events, including behavior and symptoms before and after the injury, is critical to determining if the mechanism is consistent with the injury. The timeline is used to identify when the injury would have happened and provides a framework to compare histories for consistency. If there are multiple caretakers, they should be interviewed separately. The history should include the child's development, previous injuries, birth history (including any trauma during the birth), bleeding tendency, temperament, and any prior ED visits or hospitalization. Of note, the initial history may change if the caretaker perceives any doubt on the part of the healthcare provider (5). The primary medical doctor should also be contacted for additional information.

A complete physical examination should accompany the history and detailed timeline. Examination may reveal additional injuries which may increase the suspicion of child abuse. Examinations where physical abuse is suspected should include external examination of the genitals given the strong association between physical and sexual abuse. Accidental and inflicted injuries may occur together; there are only a very small number of injuries that stand alone as indicators of inflicted injury.

Below are some common manifestations of physical abuse and neglect:

Cutaneous Injuries

Bruises are the most common manifestation of inflicted injury, but are also very common in active healthy children. All skin injuries (e.g., bruises, abrasions, lacerations, bites, and burns) should be described by location, size, and shape, keeping in mind whether they seem to fit a pattern (e.g., human bite mark, hand print, belt mark, etc.). Bruising, in addition to being well described, should be photo documented in the medical chart with a length scale (4). Color can be used for descriptive purposes but should not be relied upon to determine the age of a bruise.

Accidental bruises are more frequent and are located in areas exposed to injury in play, such as elbows, knees, skin over the anterior tibias, and bony prominences. In contrast, inflicted injuries tend to occur at sites away from the bony prominences, including the anterior and posterior neck, head, buttocks, hands, upper extremities; obscure locations include ears and frenula, which makes their inspection critical (3). Any bruising in a nonambulatory infant requires further workup for concern of possible abuse.

Burns are a specific form of cutaneous injury that may be due to child abuse. The majority of childhood burns are accidental. The most common type of inflicted burn is by scalding hot liquid. Accidental scalds typically involve hot liquids pulled and splashed on the child's upper body. To differentiate, inflicted scalds or forced immersion burns typically have a sharp line of demarcation. Inflicted burns may also be the result of the application of hot objects (e.g., cigarette burns or a hot iron) or chemical or electrical injuries (5). The depth of a burn depends on the time of exposure and temperature. For more information, please see Chapter 46.

Fractures

As with any fracture, swelling, tenderness, or disuse of an extremity may indicate underlying fracture. There may not be an overlying bruise. Rib fractures in infants, classic metaphyseal lesions, multiple and complex skull fractures, scapula fractures, fractures of the vertebral body or spinous process, as well as fractures in a

nonambulatory child are concerning for abuse. Rib fractures and metaphyseal fractures may not be clinically evident; therefore, a negative physical examination does not rule out an occult injury (3).

Abusive Head Trauma

"Shaken baby syndrome" is a popular term used to describe injuries resulting from abusive head trauma (AHT). However a greater understanding of the mechanisms and injuries associated with AHT has caused a shift in this terminology. The American Academy of Pediatrics recommends physicians abandon the term "shaken baby syndrome" since it implies a specific back and forth, acceleration–deceleration mechanism. In younger children the acceleration–deceleration more specifically will result in rotation of the head as it sits upon the neck. "Shaken baby syndrome" also does not include blunt impact as another possible mechanism. AHT is a more inclusive term, referring to mechanisms which include but are not limited to shaking (6).

The incidence of AHT during the first 2 years of life has been estimated in various studies to range from 16.1 to 33.8 cases per 100,000 infants per year (5). It is the leading cause of child abuse fatalities in infants (3). Victims of AHT may present with vague, nonspecific, poorly explained symptoms including feeding difficulty, vomiting, irritability, respiratory changes (including apnea), lethargy, seizures, hypothermia, hypotonia, or altered mental status. The most common presentation is of respiratory difficulty, apnea, or unexplained seizures, secondary to increased intracranial pressure.

Victims of AHT may present with soft tissue injuries to the scalp, skull fractures, intracranial bleeding, or parenchymal brain injuries. These injuries can occur in isolation or in combination and the evaluation may detect coexisting injuries unexplained by the mechanism offered for the initial head injury. These coexisting injuries include retinal hemorrhages (RHs), long bone and rib fractures (7).

RHs are present in 70% to 80% of confirmed cases of AHT. RHs are found in less than 10% of non-AHT. With AHT, RH are more

often bilateral and more numerous; found throughout all layers of the retina out to the periphery (ora serata) (7). With non-AHT, they are more frequently unilateral and fewer in number confined to the posterior pole or optic disc. An ophthalmologist with pediatric experience should be consulted to perform a dilated retinal examination to evaluate for RHs (7).

The fractures associated with AHT are a direct result of the mechanism. Skull fractures may be seen as the result of impact on a hard surface. Metaphyseal fractures at the ends of long bones may be seen as the result of the child's extremities flailing around during the injury or due to twisting or pulling of the extremities when the child is mishandled. Rib fractures, especially posterior-medial, may be the result of squeezing as the child is gripped around the chest during the injury. Posterior-lateral rib fractures may also be the result of squeezing, but can also result from blunt impact. With the exception of two-handed CPR in neonates and young infants CPR will usually not result in posterior rib fractures (3).

Abdominal Trauma

Although uncommon, abdominal trauma is among the leading causes of death from physical abuse. Injury can be due to blunt trauma or penetrating trauma. The most commonly injured organ is the liver, followed by spleen, hollow viscus, and pancreas (8). If the intestines, liver, or spleen have been ruptured, guarding or abdominal muscle rigidity may be noted on palpation. Abdominal bruising may be present, but is uncommon (3). Patients with altered mental status being evaluated for abuse with negative head CTs should be evaluated for occult abdominal trauma.

Neglect and Medical Child Abuse

Child neglect is the most common form of child abuse, accounting for nearly half of all child abuse fatalities. Types of neglect include physical (e.g., failure to thrive), medical, dental, poor oversight (e.g., ingestions), emotional, educational, and "other" (including exposure to domestic violence and illegal activities) (5). The

diagnosis of neglect often requires an extensive medical record review and multi disciplinary investigation.

The opposite of neglect, specifically medical neglect, is medical child abuse, formerly referred to as Munchhausen syndrome by proxy. Medical neglect refers to the child *not* receiving adequate medical treatment, while medical child abuse occurs when a child receives *too much* medical treatment (5). Medical child abuse should be considered when a child receives unnecessary and potentially harmful medical care at the insistence of a caretaker (5). As with physical abuse, the history frequently does not match the clinical status of the patient.

As with neglect, the diagnosis of medical child abuse can be difficult to make in the ED. The ED physician should consider it in the patient with multiple ED/hospital visits, multiple rare diagnoses, and the abrupt onset of symptoms with no clear medical etiology. Caretakers may list various concerns, cite diagnoses that are untrue, and request invasive procedures or hospitalization. A high level of suspicion should be maintained, and CPS should be contacted when necessary (9).

KEY TESTING

When physical abuse or neglect is suspected, testing may be indicated for diagnosis, for screening to detect other injuries, or to rule out undiagnosed medical causes to account for the injuries. Testing is based on the injury severity and age of the child.

- Children < 2-year old who have injuries or symptoms suspicious for abuse, should receive a skeletal survey to look for occult injury. A single radiograph of the entire infant ("babygram") is inadequate. Skeletal survey should be followed up in 2 weeks, to look for acute fractures not visualized on initial imaging (4).
- Children > 2-year old should have x-rays of clinically affected limbs to look for fractures (4).
- Children < 1-year old with injuries or history suspicious for abuse should *also* have a noncontrast head CT (NCHCT). Note that if the NCHCT does not yield any information and there is

high suspicion of child abuse, obtain an MRI of the head/neck with T1/T2, echo, and FLAIR (fluid attenuation inversion recovery) sequences (4).

- If AHT is suspected, CBC, PT, PTT, and DIC laboratories may be indicated since intraparenchymal damage may affect coagulation. Laboratory evaluation is guided by the clinical status of the patient and the workup should proceed as it would for any patient in critical condition to stabilize them.
- For suspected abdominal trauma, hepatic enzymes, as well as amylase and lipase should be obtained and a CT scan of the abdomen should be obtained when indicated.
- When a toxic ingestion is suspected as a result of neglect, physical or medical abuse, obtain a urine toxicology screen. There are several limitations of the available testing so a negative test may require follow-up broader more advanced toxicologic screening tests.
- If an underlying medical cause for the patient's presentation is suspected, consultation with a specialist is recommended. For example, bruises in a child do not alone require further testing, however when a bleeding disorder is of concern, screening laboratories may be indicated in addition to consultation with a hematologist.

ED MANAGEMENT

All findings on history and physical examination should be documented clearly in the medical chart. Direct quotes from the child and caregiver should be utilized. Photo documentation should be obtained and clearly labeled with the patient's name and date of presentation to the ED. There should be a clear, precise description of any injuries. All radiologic studies should be reviewed by a pediatric radiologist specifically looking for osteopenia or any indication for an underlying metabolic condition. Though abuse may still have caused the injury, the mechanism in these instances would require less force. Dating of fractures or subdural hematomas

may be imprecise and therefore should be described simply as either acute or healing.

Social work where available should be consulted to perform a family psychosocial assessment and screen for domestic violence, substance abuse, or any contact with CPS in the past. When the decision is made to contact CPS, the physician should calmly inform the parent(s) a report is being made because he or she is required to do so by state law in cases where there is an injury to a child without a clearly understood mechanism. It is generally helpful to explain what is anticipated after the report is made by informing the parents about the steps in the investigative process. Investigators will want to talk with the caretakers, often speaking with each one separately, as well as speaking to the child if he or she is old enough to relate what happened.

CRITICAL INTERVENTIONS

- Complete a thorough history and physical examination with clear documentation, including photographic documentation of injuries.
- Recognize when the history provided is inconsistent with the developmental stage of the child or with the stated mechanism of the injury.
- Consider and investigate diagnoses other than abuse.
- Order appropriate testing based on age and injury severity.
- Maintain a low threshold for contacting CPS to make a report of suspected abuse or neglect.

DISPOSITION

Emergency physicians must assess the degree of imminent risk to the child if they are discharged home. CPS will determine if it is safe for the child to go home with their caregiver(s) or if they should be placed into state custody. The child should not be discharged until there is a safety plan established. Many times if the child is in critical condition, due to AHT for instance, he/she will be admitted to the hospital.

Common Pitfalls

- Failure to identify infants who present with nonspecific symptoms as possible victims of child abuse.
- Failure to take a complete history, including developmental level of the patient, and evaluate for the mechanism of injury.
- Failure to complete a thorough photo documentation of injuries.

SEXUAL ABUSE

The sexual abuse of a child is imposed sexual activity for which the child is not emotionally, intellectually, or developmentally prepared to give consent. The sexual activity can include, but is not limited to, direct physical contact between victim and abuser (i.e., genital, oral–genital, anal–genital, breast contact, fondling, use of objects to penetrate the oral/anal/genital cavities of the victim) or can be without physical contact (voyeurism, production or viewing of child pornography, exhibitionism) (10). Adolescent patients can be victims of sexual abuse just like prepubertal children. This is distinct from adolescent sexual assault which is "any genital, anal, or oral penetration by a part of an individual's body or by an object, using force or without a person's consent" (11). Of note, the age of consent for sexual intercourse and reporting requirements to CPS, parents, or law enforcement vary from state to state (12,13).

The treatment of adolescent sexual assault is approached similarly to adult sexual assault, with some key considerations (e.g., most commonly acquaintance rape, familiarity with your state's statutes surrounding statutory rape, the developmental level of the adolescent as compared to an adult, and physical examination in adolescent is less likely to have findings than in adults) (14). Please see Chapter 135.

CLINICAL PRESENTATION

A sexual abuse victim may present to the ED in a variety of ways. For instance, a clinically stable patient may be taken to the ED after a disclosure of sexual abuse to a parent or caregiver. Alternatively parents may suspect sexual abuse has occurred as a result of unusual

physical or behavioral symptoms leading them to bring the patient to the ED. Most of these signs and symptoms are incredibly nonspecific and are frequently linked to common pediatric issues in nonsexually abused children. Examples include nonspecific abdominal pain, enuresis, encopresis, or genital or rectal itching. Behavioral complaints include sexualized behavior, changes in school performance, sleep disturbances, and phobias (10).

Patients presenting to the ED critically ill (e.g., hemorrhagic shock from vaginal or anal trauma), must initially be stabilized, making forensic evidence collection, questioning, and reporting a secondary priority (10).

DIFFERENTIAL DIAGNOSIS

"Mimics" of findings otherwise concerning for sexual abuse include vaginitis, vulvar dermatitis, labial adhesions, anal fissures, genital/anal infections, foreign bodies, vascular problems, neoplasia, urethral prolapse, ureterocele, and lichen sclerosus (5). Accidental anogenital injury is uncommon with the exception of straddle injuries which generally have clear, unambiguous histories. Normal and developmental variations to the anogenital area should also be considered and referenced, in prepubertal females particularly in terms of hymen anatomy (5).

ED EVALUATION

The vast majority of the time in sexual abuse, the physical examination is normal, making the patient's history critical. It is important to know your local resources and state policies. Assuming that a child advocacy center (CAC) or child abuse pediatrician (CAP) is available, a full forensic interview will take place later under optimized conditions. ED physicians may not have training in forensic interview techniques or the time necessary to conduct such an extensive interview but this should not prevent a thorough medical history from being obtained (5). Before beginning, the physician should explain his/her role, the steps in the evaluation, and all elements of the physical examination, to minimize anxiety

for the patient and family members. The physician should take time to build rapport and trust with the child to facilitate a more relaxed and cooperative examination. When appropriate, a brief history should be obtained from the child directly and separately from the parent for the purposes of medical diagnosis and treatment (5). The child's developmental stage should be considered to ensure that the questions asked can be be reliably answered based on language acquisition. Very young children (ex. less than 6 years old) are susceptible to repeated and/or leading questioning in part because of their dependence on adults. When an adult repeatedly asks a young child the same questions, there is the risk that the child will give different answers to please the adult. It is therefore advisable that very young children not be interviewed in this setting (5). When talking to an older child or adolescent who is developmentally appropriate, questions pertinent for the patient's medical care should include a history of the events—specifically, the frequency of contact, most recent contact, type of contact (penile–oral, penile–vaginal, penile–anal, fondling), any physical symptoms or injuries, condom use, and abuser characteristics (e.g., known to be HIV positive) (5). It is also important to determine the mental state of the patient and screen for suicidal ideation and/or depression where appropriate.

The physical examination should begin with a general examination to check for other physical injuries that may require photo documentation.

If the history provided reveals the last contact occurred within the previous 72 hours or there are symptoms concerning for an acute injury (e.g., anogenital pain, anogenital bleeding), emergent anogenital examination should be performed. When the type of contact would not necessitate evidence collection or examination (e.g., touching without penetration), more than 72 hours has passed, or there are no symptoms (e.g., bleeding, pain, discharge), it is not necessary to perform a genital examination in the ED. As long as the patient is safe, examination by a skilled child abuse pediatrician can be scheduled in the outpatient setting (10).

Emergent anogenital examination is necessary when there are symptoms and/or the patient presents within 72 hours of the last contact. Of note, a speculum examination is not recommended at the time of presentation unless there is vaginal bleeding, and concern for intravaginal injury. Surgery or gynecology should be consulted in that case. Anesthesia will likely be necessary in the prepubertal child and should be strongly considered in the adolescent patient if she is unable to cooperate with the examination (5). It is important to note that, unlike a prepubertal patient, an adolescent patient has the right to refuse any part of the examination.

When anesthesia is not required, the patient should be examined in the most comfortable position possible. For prepubertal females, the supine frog-leg position provides the examiner with a clear view of the anogenital structures (5). When the patient is supine, the examiner can lightly grasp the labia and pull downward, outward, and anteriorly (labial traction). The prone knee-chest position allows better viewing of the posterior hymen and upper vagina. This position should be used to confirm a suspected hymenal injury. The use of a gynecologic examination table in the lithotomy position can be used with older children and adolescents. Always remember to document the patient's Sexual Maturity Rating (5).

The vast majority of the time the genital examination will be normal even if the child gives a clear history of penetration or the abuser confesses to penetration. A normal physical examination neither confirms nor excludes a history of sexual abuse. Examination findings should be documented as nonspecific, suggestive, or indicative of recent trauma. Concerning findings on physical examination of prepubertal victims include vaginal lacerations, complete hymenal transections, deep clefts, bruises or abrasions of the hymen, fossa navicularis, and posterior fourchette (5).

KEY TESTING

- Forensic evidence collection (forensic evidence kit [FEK], aka "rape kit") and laboratory workup should be considered when (1) presentation is within 72 hours of disclosure of the last sexual contact *and* (2) the sexual contact includes penetration, *or* there are findings on physical examination that are suspicious for acute injury.
- Policies and procedures for the FEK collection vary by state. The FEK consists of a series of swabs used to identify potential DNA evidence left from the abuser on the victim (e.g., semen, secretions, saliva, blood, hair). The FEK also collects the child's clothing, including underwear, as well as linens associated with the abuse as these are more likely to yield positive findings on forensic analysis.
- Specially trained, nonphysician medical personnel, such as pediatric sexual assault nurse examiners (pedi-SANEs), are able to assist in the medical and forensic evaluation of children and adolescents. ED physicians should know the protocol at their institutions where pedi-SANEs are available (15).
- Routine screening for STIs, including pregnancy testing, in postpubertal victims is recommended. More selective criteria are applied to prepubertal patients. These criteria include symptoms concerning for an STI, an abuser known to have an STI or is at high risk, the patient's sibling or close contact has an STI, there is evidence of vaginal, anal, or oral penetration, evidence of ejaculation, and parent/patient request (10). If there is evidence for one STI, the child should be tested for other STIs as well.
- Gonorrhea (GC) and Chlamydia (CT) are the most common STIs identified in sexually abused children and adolescents. Cultures are recommended as the test of choice in this population. Of note, recent literature suggests that urine nucleic acid amplification tests (NAATs) for GC and CT are more sensitive than cultures and are less invasive than cultures which may be preferable (11). When cultures are obtained from females, they should be vaginal only (not cervical). Culture remains the preferred method for boys and for nongenital specimens (pharynx and rectum) (12).

- Serologic testing for hepatitis B, hepatitis C, human immunodeficiency virus, and syphilis should be obtained if indicated or if requested by the patient or family. Table 290.1 outlines the implications of various STIs and the relationship with sexual abuse in prepubertal children (10).

TABLE 290.1
Implications of Commonly Encountered STIs for the Diagnosis and Reporting of Sexual Abuse of Infants and Prepubertal Children

STD Confirmed	Sexual Abuse	Suggested Action
Gonorrhea[a]	Diagnostic[b]	Report[c]
Syphilis[a]	Diagnostic	Report
HIV infection[d]	Diagnostic	Report
Chlamydia trachomatis infection[a]	Diagnostic[b]	Report
Trichomonas vaginalis infection	Highly suspicious	Report
Cyanea acuminate infection[a] (anogenital warts)	Suspicious	Report
Herpes simplex (genital location)	Suspicious	Report
Bacterial vaginosis	Inconclusive	Medical follow-up

Unless there is a clear history of autoinoculation.
[a]If not perinatally acquired and rare nonsexual vertical transmission is excluded.
[b]Although the culture technique is the "gold standard," current studies are investigating the use of nucleic acid amplification tests as an alternative diagnostic method in children.
[c]To the agency mandated in the community to receive reports of suspected sexual abuse.
[d]If not acquired perinatally or by transfusion.

ED MANAGEMENT

If a postpubertal female patient presents within 72 hours of last contact, emergency contraception should be offered. In addition, if the postpubertal patient presents within 72 hours or is having symptoms suspicious for an STI, postexposure prophylaxis for STIs should be offered. STI prophylaxis is not routinely recommended in prepubertal females because of the low frequency of acquiring an STI after being sexually abused. Treatment is warranted if the

history or physical examination is strongly suggestive of an STI (10). Please see Chapter 184 for more specific details on STIs and their treatment.

Of note, sexual abuse has resulted in the transmission of HIV. The consideration for HIV postexposure prophylaxis requires the patient present within 72 hours of exposure; victims of sexual abuse are usually exposed over a longer period of time and therefore may not benefit from prophylaxis. With long-standing sexual abuse, assessment of risk factors pertaining to the abuse (e.g., abuser is known HIV positive) and consultation with a pediatric infectious disease specialist is critical (16).

All suspected cases of sexual abuse should be reported to the appropriate law enforcement agency and CPS based on your state's reporting laws.

CRITICAL INTERVENTIONS

- Perform anogenital examination of a prepubertal child only if the child presents within 72 hours of anogenital contact or if the patient is having acute symptoms.
- If last contact was within 72 hours, perform an examination using a FEK, clinically relevant laboratory studies, and prophylaxis when indicated.
- Report all cases of suspected sexual abuse the appropriate law enforcement agency and CPS based on your state's reporting laws.

DISPOSITION

A more detailed forensic interview as well as detailed genital examination with the use of colposcopic magnification is usually performed by appropriately trained personnel at a regional CAC. Follow-up examinations by specialists can affect the interpretation of trauma and detection of STIs. They are recommended to assess healing and provide reassurance. Significant injuries or laboratory test results require follow-up, usually within a week of the initial evaluation (17). In circumstances in which transmission of syphilis,

HIV, or hepatitis B is a concern but baseline tests are negative, repeat testing approximately 6 weeks, 3 months, and 6 months after the last suspected sexual exposure is recommended to allow time for antibodies to develop (12). In addition, mental health referrals should be made.

Common Pitfalls

- Decision to perform examination of genitalia when not indicated.
- Failure to provide medical follow-up as well as mental health referrals.
- Failure to perform FEK, appropriate testing, and administer appropriate prophylaxis when indicated.

CHAPTER 291

Ventricular Shunt Problems and Technology-Dependent Children

Lila O'Mahony and Rob Cloutier

Children with chronic conditions are a rapidly growing population and require emergency evaluation and care more frequently than other children (1–4). A subpopulation of these children are dependent on medical devices for a broad range of congenital problems or acquired illnesses. These devices include cerebrospinal fluid (CSF) ventricular shunts, tracheostomy tubes, enteral feeding tubes, and indwelling central catheters. Many of these children have complex chronic conditions and may require urgent or emergent transfer to a pediatric center that can provide subspecialty or critical care.

Parents and caregivers are often experts regarding their child's medical conditions and associated equipment, and are often excellent sources of information for the emergency physician. Caregivers are often able to note the mildest of alterations in a child's behavior or mental status and serve as a vital early warning system for illnesses or complications.

CEREBROSPINAL FLUID SHUNTS

CSF shunt placement, usually for the treatment of either congenital or acquired hydrocephalus, is the most common neurosurgical procedure performed in children (5). Untreated hydrocephalus can lead to increased ICP, brain injury, and death (6); however,

complications associated with CSF shunts are relatively common and can also cause significant morbidity and even death (7).

CSF shunts are catheters inserted into the ventricles or other CSF-containing structures in the brain and then threaded under the skin from the skull to the terminal location such as the right atrium, pleural cavity, or (most commonly) the peritoneum. There are three components to the shunt: (a) A proximal catheter that drains one of the cerebral ventricles or areas of CSF accumulation, (b) an extracranial one-way valve to prevent backflow of CSF, and (c) a subcutaneous tunneled distal catheter. Some shunts also have a single or double reservoir system located adjacent to the opening in the skull and can be accessed percutaneously to collect CSF. The catheters and valves have radiopaque markings to enable radiographic visualization (Table 291.1).

TABLE 291.1
Congenital Hydrocephalus and Acquired Hydrocephalus

Congenital Hydrocephalus	Acquired Hydrocephalus
Congenital cysts	Neoplasm
Intraventricular hemorrhage of prematurity	Infection
Congenital brain malformations	Trauma

COMPLICATIONS: SHUNT MALFUNCTION AND INFECTION

The cause of shunt malfunction may be mechanical (e.g., broken tubing) or nonmechanical (e.g., infection), or a combination of the two. Shunt malfunction occurs most commonly in the first 12 months following placement, and accounts for about 10% of all shunt malfunctions (8). After the initial year post-placement, the rate of shunt malfunction falls to about 5% (9).

Obstruction of CSF flow is the most common type of shunt malfunction. The three most common sites of obstruction are the proximal catheter, the proximal valve, and the terminal end of the distal catheter. Shunt catheters can also become disconnected at any point along their trajectory, most commonly in the neck region (10).

Disconnections are often associated with improper use of connectors distal to the valve or fracture of the shunt tubing that can occur with age and calcification over time. A less common complication is *migration* of the tip of the shunt catheter. The catheter tip can migrate into or traverse intra- and extra-abdominal organs including the bladder, rectum, scrotum, and lungs. This is in part due to the extra length of tubing placed in the abdominal cavity to correspond to the child's future growth. Other complications are organ specific and depend on where the catheter terminates, and may include intraperitoneal CSF collections or pseudocysts which may or may not cause peritonitis.

Obstruction, disconnection, and catheter migration often lead to complications associated with inadequate CSF drainage. However, overdrainage can also be a problem. While rare, overdrainage can lead to ventricular collapse and "slit ventricle syndrome," which manifests as orthostatic hypotension, subdural fluid collections, craniosynostosis, ventricular compartmentalization, and cerebellar tonsillar herniation (11).

Shunt infections include the shunt hardware, the overlying tissues, or the distal terminal sites (typically within the peritoneum) and occur primarily through direct contamination or hematogenous seeding. The reported incidence averages 10% to 15% (11), the majority occurring within the first 6 months post-placement (12,13). Like other bacterial infections of the CNS, these infections can be responsible for severe neurologic injury or death (Table 291.2).

TABLE 291.2
Risk Factors for Infection

• Premature birth	• CSF shunt leak
• Patient age <6 mos	• Prior shunt infection
• Shunt placed/revised <6 mos ago	• Revision soon after placement

Data from McGirt MJ, Zaas A, Fuchs HE, et al. Risk factors for pediatric ventriculoperitoneal shunt infection and predictors of infectious pathogens. *Clin Infect Dis*. 2003;36:858–862; Simon TD, Whitlock KB, Riva-Cambrin J, et al. Revision surgeries are associated with significant increased risk of subsequent cerebrospinal fluid shunt infection. *Pediatr Infect Dis J*. 2012;31:551–556.

CLINICAL PRESENTATION

Children may have subtle or fulminant presentations of shunt complications. Paying close attention to the history and concerns relayed by the parents or caregivers cannot be overemphasized (14). Presenting symptoms of a shunt malfunction or obstruction may be subtle (mild irritability) or profound (signs of impending herniation and cardiopulmonary instability). Cranial nerve palsies, visual impairment, and hemiparesis represent atypical presentations (14). Headaches are a common complaint in children with shunts, and the character of the headache may help diagnose malfunction. Severe and progressive headaches are more likely to be associated with increased ICP, whereas postural headaches may be associated with slit ventricle syndrome or low-pressure conditions (Table 291.3).

TABLE 291.3
Shunt Malfunction/Obstruction

Symptoms	Signs
• Lethargy	• Bulging, tense fontanelle
• Irritability	• Widely split sutures
• Headache	• Shunt site swelling
• Nausea/vomiting	• Papilledema
• Visual changes	• Engorged head veins
• Developmental delay	• Cranial nerve palsies
• Incontinence	• Hyperreflexia
• Seizure (late)	• Cushing triad (late)

The presenting symptoms of shunt infection may be nonspecific, or suggestive of other entities, including shunt malfunction. Importantly, fever is not always present and is rarely the sole manifestation of shunt infection. Infection can include any portion of the shunt system. While seizure activity is a negative predictor of shunt malfunction, elevated ICP caused by shunt failure must still be considered (15,16). Lastly, it is important to remember that a patient can have concurrent shunt malfunction and infection and thus present with clinical evidence of both problems (Table 291.4).

TABLE 291.4
Shunt Infection

Symptoms	Signs
• Chills, fever • Nausea/vomiting • Irritability • Abdominal pain • Headache	• Fever • Behavioral change • Erythema or swelling at shunt site or along catheter track • Peritonitis • Signs of shunt malfunction

DIFFERENTIAL DIAGNOSIS

Symptoms of shunt malfunction and infection are largely nonspecific and other common pediatric illnesses, such as acute gastroenteritis, urinary tract infection, and otitis media, should be considered once shunt function has been evaluated.

ED EVALUATION

Important history includes the indication for and date of the initial shunt placement, postoperative complications, and any history of shunt malfunctions, infections, or revisions. It is important to ask about signs and symptoms that may have accompanied previous failures. The shunt itself should be examined and palpated for any signs of infection (warmth, tenderness, or erythema) or malfunction (broken tubing or subcutaneous collection of CSF). The shunt catheter can be located as it exits through a hole in the skull, travels subcutaneously just inferior to and behind the ear, and continues down the neck to the chest. For a ventriculoperitoneal shunt, the catheter travels anterior to the clavicle, passes through the subcutaneous tissue overlying the chest wall, and ultimately enters the peritoneal cavity. Of note, when inspecting shunts that have been recently placed, incision sites should be carefully examined for evidence of infection.

Imaging and laboratory studies are often indicated in suspected shunt malfunction or infection. Standard imaging should include a plain radiograph “shunt series” and either a noncontrast computed tomography (CT) or magnetic resonance image (MRI) of the head to

assess ventricular size and changes from prior studies. Some shunt valves will need to be reprogrammed following an MRI and require an on-site individual trained at this procedure. The shunt series images the entire course of the shunt, including the skull, neck, chest, and abdomen, to reveal catheter fracture, kinking, disconnection, dislocation, or migration. Finally, an abdominal ultrasound or CT scan is indicated if there is concern for an intra-abdominal process such as intra-abdominal pseudocyst around the distal tip.

A complete blood count with differential, blood cultures, electrolytes, and a coagulation screen are commonly recommended for the evaluation of a potential shunt malfunction or infection. A neurosurgeon should be consulted before a diagnostic puncture is performed for aspiration ("tap") of a ventricular shunt. For patients who are not critically ill, a shunt tap is performed to measure the opening pressure and collect CSF for laboratory analysis (cell count, protein, glucose, Gram stain, and culture) to detect possible infection. Rarely, a patient with a ventricular shunt may present to the ED with signs of cardiorespiratory failure due to elevated ICP (unilateral fixed and dilated pupil, posturing, apnea). In this unique circumstance, it may be appropriate to perform a therapeutic shunt tap without first consulting a neurosurgeon.

KEY TESTING

- Head CT or brain MRI
- Radiographic shunt series
- Laboratory studies as indicated by presentation and differential diagnosis

ED MANAGEMENT

The time between the onset of symptoms and coma from shunt failure may be only a few hours (17). A patient with a suspected ventricular shunt problem should be seen in the ED by a neurosurgeon, regardless of the results of diagnostic tests. CT scans can be notoriously unchanged from baseline despite an acute shunt

malfunction. In situations where evaluation by a neurosurgeon is not possible, transferring the patient to another facility where such services are available may be the best option.

For patients with confirmed shunt infection, empiric antibiotics should be administered to cover both common gram-positive and gram-negative pathogens. A third-generation cephalosporin (e.g., ceftriaxone, cefotaxime) and vancomycin are recommended choices for initial therapy to cover typical pathogens (commonly *Staphylococcus* species), and penetrate well into the CNS. Patients with confirmed shunt malfunction or obstruction require a surgical revision. The timing of the revision depends on the patient's clinical condition and the availability of the neurosurgeon; severe symptoms require immediate repair.

KEY INTERVENTIONS

- Obtain history of the reason for and date of shunt placement, prior complications, and infections.
- Obtain a shunt series and noncontrast CT.
- Transport the patient as necessary to a facility where definitive care can be provided.

DISPOSITION

For patients who require interfacility transfer, if possible, complete any invasive procedures that are likely to become necessary (endotracheal intubation, central line placement, etc.) while the patient is still in the ED, since space and personnel advantages greatly increase the chances for success.

Any child with suspected or confirmed shunt infection or malfunction requires hospital admission. If the diagnostic workup for shunt malfunction is negative and the patient is examined and cleared by a neurosurgeon, the child can be safely discharged from the ED. For children discharged home, it is important to provide clear return instructions and recommendations for outpatient follow-up.

Common Pitfalls

- Failure to recognize a shunt malfunction or infection associated with nonspecific patient complaints. Complaints such as "decreased activity" or "poor appetite" may be due to a viral illness, but warrant a focused shunt evaluation in patients with a shunt.
- Failure to review previous head CT or MRI scans.
- Failure to obtain neurosurgical consultation in the ED.

TRACHEOSTOMY TUBES

Tracheostomy tubes share two common attributes: (1) A primary cannula, and (2) an obturator that is inserted into the primary cannula for all replacements, whether routine or emergent. Parents can usually provide specific details about their child's tracheostomy and tracheostomy tube (**Tables 291.5** and **291.6**).

TABLE 291.5
Tracheostomy Tubes

- Single cannula: Neonates, younger children
- Double cannula with outer sheath: Older children
- Fenestrated tubes: Redirects air into upper airway, allows child to speak and breathe through nose and mouth
- Cuffed or uncuffed

TABLE 291.6
Tracheostomy Complications

- Decannulation
- Obstruction
- Granuloma formation at stoma
- Superficial bleeding at cannulation site
- Hemorrhage due to tube erosion into local blood vessel
- Creation of false passage with reinsertion
- Bronchospasm
- Infection
- Tracheitis
- Bronchitis
- Pneumonia

CLINICAL PRESENTATION

Children with an obstructed or dislodged tube (one of the most common complications) (18) range from those who appear well to those with impending respiratory failure. This depends on their degree of tracheostomy dependence, which can range from none to complete dependence on mechanical ventilation. Infection should be suspected if there are acute changes in tracheal secretions such as increased thickness, quantity, new color, or new odor, especially if accompanied by fever.

ED EVALUATION, MANAGEMENT, AND DISPOSITION

In the case of tracheostomy tube obstruction or displacement, it is important to recall that caregivers routinely replace tracheostomy tubes outside the hospital setting. Thus, a patient whose dislodged or obstructed tube has not been easily managed by a parent or caregiver must be considered to have a high-risk airway. Ideally, an otolaryngologist should be consulted prior to attempts at tube replacement in case the tube does not easily pass, if bleeding occurs, or other significant surgical concerns arise, especially with a recently created tracheostomy site. Patient positioning and careful preparation for emergent airway management are critical and should include tracheostomy-specific suction, oxygen delivery, and humidification systems. Place a towel roll under the child's shoulders to hyperextend the neck for optimal visualization of the tracheostomy site and to help open the airway distally. Identify the type and size of tracheostomy needed for replacement, and if possible, have a second device, a half-size smaller, available if edema, scar tissue, or anatomic factors prevent replacement with the original size. If the type of device and tube size are not known, an appropriately sized endotracheal tube may serve as an interim solution, but it should not be advanced more than 2 to 4 cm into the stoma.

An appropriately sized endotracheal tube and airway setup should always be available in case an airway cannot be established through the tracheostomy site and emergent orotracheal intubation becomes necessary (18). Tracheal suctioning may help relieve mucus

plugging, but it is important to limit suctioning to only 10 to 20 seconds to prevent hypoxemia and further respiratory compromise. Humidified oxygen should be administered. Albuterol may be administered liberally by this route if there is thought to be bronchospasm.

Prior to placement of the new tube, verify balloon integrity and lubricate the tip. Similarly, be sure to deflate the balloon on the old tracheostomy tube prior to removing it. Once the old tube has been removed, carefully place the new tube into the recently vacated stoma. To minimize the chance of creating a false passage, do not force the tube into the tract. If there is significant respiratory distress, failure to pass the tube easily should prompt consideration of orotracheal intubation.

If there is concern about tracheitis or pneumonia, tracheal aspirate samples and a chest radiograph should be obtained. Consider empiric antibiotics to cover typical pathogens: *Staphylococcus* species, *Haemophilus influenzae B,* and *Moraxella catarrhalis.* Disposition from the ED depends on the patient's overall clinical status and specific tracheostomy needs. Children requiring new or increased oxygen support, intravenous antibiotics, ongoing pulmonary care, or subspecialty consultation should be hospitalized.

ENTERAL FEEDING TUBES

Enteral feeding tubes are placed for diverse indications. Some children depend on them for primary nutrition and hydration, whereas others have to be used only for supplemental nutrition or medication administration. Feeding tubes placed via the nasopharynx, such as nasogastric (NG) and nasoduodenal (ND) tubes, are typically temporary, while gastrostomy (G) and gastrojejunostomy (GJ) tubes, which are placed through the abdominal wall, are more permanent. Feeding tube complications may be categorized as those related to the anatomical location of the tube and the surrounding tissues, or those related to the tube itself (e.g., dislodgement or breakage) (Table 291.7) (19).

TABLE 291.7
Complications of Enteral Feeding Tubes

All Tubes	Nasogastric/ Duodenal	Gastrostomy	Gastrojejunostomy
Dislodgement	Sinusitis	Gastroesophageal reflux	Diarrhea
Obstruction	Nasoesophageal irritation	Peristomal infection	Tube migration
Gastric distention	Aspiration	Abdominal wall abscess	Bowel perforation
		Peritonitis	Intussusception
		Gastric perforation or hemorrhage	Peritonitis
		Gastrocolic fistula	Peristomal infection
		Gastric ulceration	Abscess
		Gastric outlet obstruction	

Stomal complications include dermatitis, bleeding granulation tissue, peristomal cellulitis, and superficial fungal infection.

CLINICAL PRESENTATION

The majority of children appear well, though others may complain of abdominal distention and pain. Dislodgement, especially of G tubes, is the problem most commonly seen in the ED (20).

ED EVALUATION, MANAGEMENT, AND DISPOSITION

NG and ND tubes can be replaced in the ED. ND tubes are more challenging because the tip must pass through the pylorus; placing the child on his or her right side may help with movement through the pylorus. Dislodged G tubes require urgent replacement to prevent closure of the stoma and tract. A temporary catheter (e.g., Foley catheter) may be inserted in place of the actual device to preserve the stomal tract until a more permanent replacement tube is secured. A G tube that has been placed surgically within 2 months, and especially within 2 weeks, should be replaced by the specialty service that initially placed it, because of the increased risk of creating a false tract within the incompletely healed abdominal wall (21). Analgesia and anxiolysis should be considered prior to tube replacement to help with relaxation of the abdominal wall musculature. Dilators may be required to facilitate replacing the

tube, but recently created tracts (i.e., less than 30 days old) should not be dilated.

GJ tubes require interventional radiology or general surgery consultation for replacement or repair. If there is concern for an abdominal wall abscess, ultrasound is an ideal initial imaging modality. Adjunctive laboratory studies should be obtained only as clinically indicated (e.g., for suspected infection or in an ill-appearing child). Children with enteral feeding tube complications often require admission to the hospital for intravenous hydration, nutritional support, medication administration, or surgery as indicated, until the tube can be satisfactorily replaced. If the tube is replaced in the ED, the position should be verified either clinically or by a contrast-enhanced imaging study; the child can then be discharged home with routine follow-up.

INDWELLING VENOUS CATHETERS

Indwelling venous catheters, often tunneled beneath the skin, may provide access through externalized tubing (e.g., Hickman device), or a subcutaneous reservoir (e.g., Port-a-cath device). They can vary in length, diameter, and number of lumens or access ports. Special equipment and specific procedural steps are necessary to access these lines. Complications may be mechanical, including dislodgement, breakage, or obstruction, or nonmechanical, including infection and air embolism. Overall, the most common complications are obstruction and infection (22).

CLINICAL PRESENTATION

Dislodged, broken, or fractured indwelling catheters may present with bleeding; a bulge, pain, defect, or swelling at the catheter site; head or neck swelling; respiratory distress; arrhythmia; or signs of cardiac tamponade. Obstruction presents with difficulty drawing back, infusing, or flushing through the line. Families will often have tried to troubleshoot this type of complication at home prior to presenting to the ED. A catheter-related infection may present with local signs and symptoms such as erythema and swelling, or the child may have systemic symptoms such as fever and tachycardia.

Immunocompromised children may not be able to mount a local inflammatory response and may present with more subtle symptoms. These patients are at high risk for disseminated infection and should be evaluated promptly. Air embolism should be suspected in patients with an acute onset of tachypnea, tachycardia, hypotension, or altered mental status.

ED MANAGEMENT AND DISPOSITION

Dislodged or broken catheters should be clamped proximally and repaired as per local institutional practices or replaced as indicated by the appropriate surgical service. Obstruction can sometimes be relieved by infusion of a fibrinolytic, but if this is unsuccessful surgical consultation is warranted. Use of these agents should follow individual institutional guidelines. If a catheter or blood infection is suspected, obtain blood cultures and initiate empiric antibiotics. Immunosuppressed children should be evaluated promptly and monitored closely. Further laboratory and imaging studies should be guided by the child's clinical status. If air embolism is suspected, the child should be placed in Trendelenburg position on the left side while the catheter is clamped and oxygen applied. If the catheter cannot be repaired in the ED, or if infection is suspected, hospital admission is likely to be necessary until definitive repair can be scheduled.

PART 6 • ADMINISTRATIVE AND CLINICAL ISSUES

CHAPTER 292 Pediatric Interfacility Transport

Lila O'Mahony and George A. Woodward

Interfacility transport is an integral component of the continuum between optimal emergency and definitive care of acutely injured or ill pediatric patients, and when executed safely, efficiently, and by appropriately skilled teams, contributes to improved patient outcomes (1–4). Given that 89% of acutely injured or sick children are initially cared for at hospitals that typically do not have pediatric specialty or critical care services (5); a substantial number of children will require transfer to a higher level of pediatric care (Fig. 292.1).

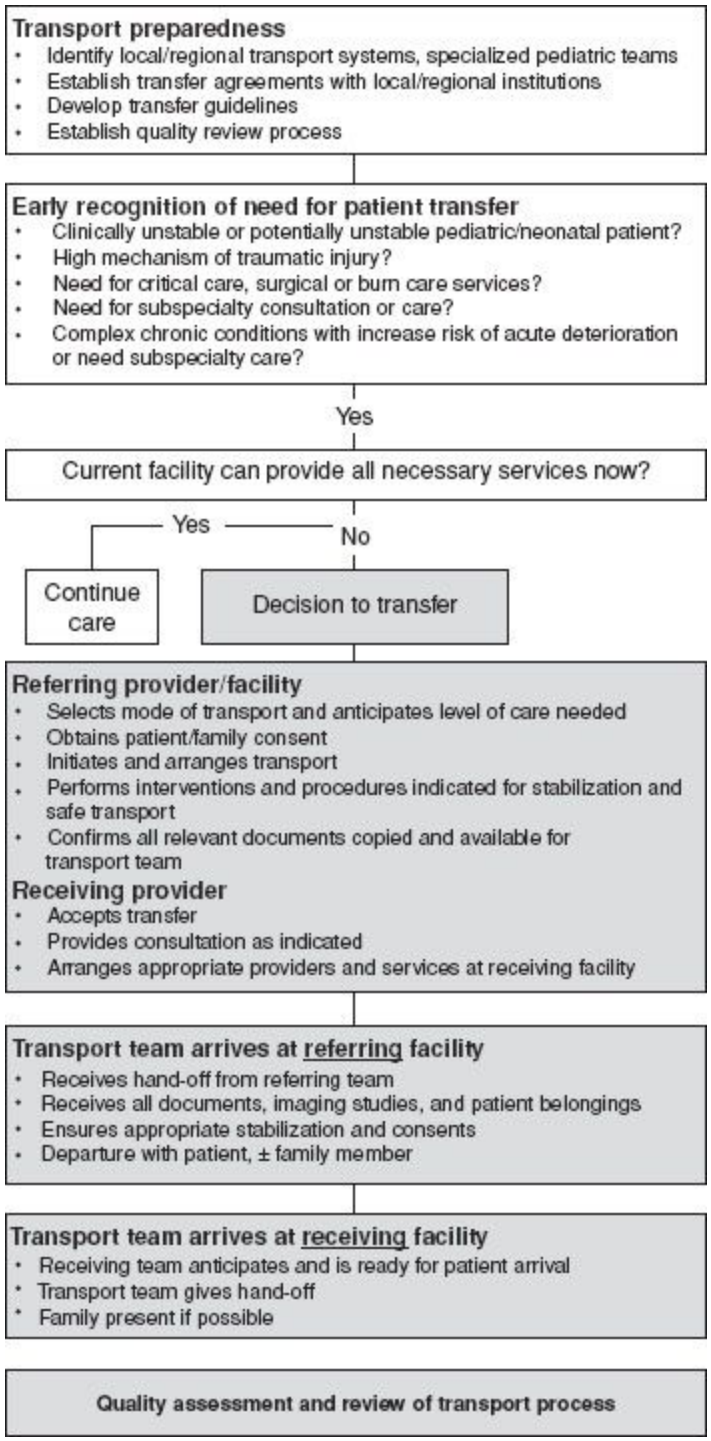

FIGURE 292.1 Pediatric interfacility transfer algorithm.

It is imperative that referring and receiving hospitals have processes and resources to safely and efficiently transfer pediatric patients. Ideally, these should be identified in advance to ensure

optimal preparation. Some hospitals have pre-existing agreements with facilities that have comprehensive pediatric services outlining expectations and conditions, as well as the standard mode of transfer for critically ill or injured patients. A practical resource for the development of such guidelines is the 2013 "Interfacility transfer tool kit for the pediatric patient," published by the Emergency Nurses Association, Emergency Medical Services for Children, and the Society of Trauma Nurses (http://www.ena.org/practice-research/Practice/Pages/Toolkit.aspx).

MEDICAL LEGAL ISSUES FOR REFERRING AND RECEIVING PROVIDERS

The Emergency Medical Treatment and Active Labor Act (EMTALA) is the cornerstone of civil transport regulation. It applies specifically to clinically unstable patients and is meant to (1) protect patients from being denied appropriate care due to an inability to pay and (2) prevent institutions from inappropriately transferring patients due to an inability to pay when the institution is able to provide needed care. Under EMTALA, referring providers are responsible for (1) stabilizing a patient within the capabilities of their institution, (2) initiating the transport process, and (3) selecting the mode of transportation, whether air or ground, and (4) the level of care the patient should be transferred to. In addition, referring providers ensure that patient care during transport remains at the level initiated and does not place the patient at undue risk. On the receiving end, providers and hospitals are responsible for ensuring they are able to provide the services the patient requires. Receiving providers and transport-related supervisors may act as consultants to the referring team to optimize ongoing care and select an appropriate transport mode. However, unless the receiving physician provides medical advice, or is serving as the transport's online medical control physician or provides the transport service, accepting institutions are not legally responsible for patients' care until they arrive at the receiving facility. Under EMTALA, there are

circumstances under which a receiving provider may deny acceptance of a patient transfer. Caution must be taken when considering the determinants of an individual's clinical "stability"; for under EMTALA, unstable patients cannot be denied transfer if the receiving facility has the capability to treat them (Table 292.1).

TABLE 292.1
Acceptable Conditions for Refusing Transfer of a Pediatric Patient

- Risks of transfer outweigh the benefits
- Patient can be realistically and properly cared for at referring facility

MODE OF TRANSPORT AND TEAM COMPOSITION

Referring institutions must appreciate the constraints of geography, traffic, weather, and other pertinent issues affecting transport logistics. These factors must be carefully weighed when selecting the composition of the transport team and the mode of transport.

Not all transport teams have comparable pediatric skills, experience, or equipment. Transport providers and teams lie on a spectrum from volunteers to basic emergency medical technicians with limited pediatric-specific skills to highly trained specialized pediatric and neonatal critical care teams. Awareness of the skill level and clinical capabilities of available transport teams will aid in the selection of the most appropriate transport team and mode (6–8).

When transferring critically ill children, the referring provider should strongly consider a team with specialized pediatric critical care skills since care by such providers is associated with decreased morbidity, improved survival, and better outcomes (1). While use of such a team may result in a longer period of stabilization at the referring facility, it allows for the initiation and continuation of consistent treatment at both facilities and ensures that an appropriately skilled team is able to respond to critical events or changes during transport. This is a fundamental difference from prehospital practice where the concept of rapid transfer and the

“golden hour” to definitive care is often emphasized (9). In locations or circumstances where specialized teams are not available, the referring provider should ensure that a team is selected which can meet the patient’s needs at the highest level without compromising clinical care. Any appropriate treatments initiated at the referring facility should be continued during transport.

Neonatal transfers are often due to critical illness, congenital disorders, and the need for subspecialty or surgical care not available at a referring institution. Critically ill newborns are infrequent patients in most emergency departments, but may present in the context of trauma, a complicated home birth, or an unexpected precipitous delivery. Neonates who are critically ill or who have the potential for acute decompensation, such as those who are premature or of very low birth weight, require providers with special skills in assessment, management, and procedures, including vascular access and neonatal airway management. Thus, these patients should be transported by specialty teams with the highest level of pediatric and neonatal skills and expertise.

Travel distance to a referral center is a major factor to consider. Ground transport is always an option with an appropriately composed team. As a general rule, distances between 20 and 100 miles may warrant rotor wing aircraft and distances greater than 100 miles may dictate the need for rotor or fixed wing aircraft. These rules of thumb must be weighed against many factors. For example, a critically ill patient 10 miles from a referral center may be better served by rotor wing transport than ground transport during rush hour in an urban setting, while the same patient may travel 300 miles by ground in a rural area with dangerous winter weather that precludes flying.

Pediatric patients, their parents, and their healthcare providers will benefit from maintaining a family centered, supportive, and safe environment for the child, which in most circumstances means enabling parents to travel with their child (10).

CHAPTER 293

Death, Catastrophic Illness, and Parental Presence in Critical Cases

Karen O'Connell, Phyllis L. Hendry, and Mardi Steere

Emergency physicians and prehospital care providers are often faced with the responsibility of telling a family that their child has died or is suffering from a catastrophic illness or injury. In the emergency department (ED), the hectic surroundings and the lack of acquaintance with the family and patient add to the challenge of this intensely difficult situation. Death in an infant or child carries unique emotional, bereavement, and coping challenges for families and staff.

EPIDEMIOLOGY OF INFANT AND PEDIATRIC DEATH

In 2011 in the United States, there were 23,910 reported infant deaths and 20,192 reported child and adolescent deaths (1). Approximately half of all pediatric deaths in the United States occur in the first year of life, with two-thirds of those occurring in the neonatal period (<28 days of life). The 2011 infant mortality rate (IMR) in the United States was reported as 6.05 deaths per 1,000 live births (1). This rate had been steadily declining over the past 40 years and almost halved between 1980 and 1995. In 2002, the IMR started to increase, a change potentially related to the increasing incidence of low birth weight (LBW) (<2,550 g). LBW is one of the most important predictors of infant mortality and correlates with the percentage of preterm births, which has increased by 20% since 1990 and continues to rise. There continues to be wide variation in

IMRs as reported by race and Hispanic origin, with non-Hispanic black newborns more than twice as likely as white and Hispanic infants to die in the first year of life.

More than half of all infant deaths in 2011 were attributable to five leading causes (Table 293.1): congenital malformations (20.8%), disorders relating to short gestation and LBW not otherwise classified (17.2%), sudden infant death syndrome (SIDS) (7.2%), maternal complications of pregnancy (6.6%), and unintentional injuries (4.6%). Patterns of leading causes of infant mortality have not changed over the past decade.

TABLE 293.1
Leading Causes of Infant Mortality in the United States in 2011

Cause of Infant Death	Percentage (%)
Congenital malformations	20.8
Disorders relating to short gestation and low birth weight	17.2
Sudden infant death syndrome	7.2
Maternal complications of pregnancy	6.6
Unintentional injuries	4.6

Adapted from Hamilton BE, Hoyert DL, Martin JA, et al. Annual Summary of Vital Statistics: 2010–2011. *Pediatrics*. 2013;131(3):548–558.

The death rate for children decreases significantly after the first year of life. In 2011, the death rate for children aged 1 to 19 years was 25.6 per 100,000 population (1). Unintentional injures remain the leading cause of death in all children older than 1 year of age, accounting for 35.6% of deaths, followed by assault (homicide) (11.4%), intentional self-harm (suicide) (10.1%), and malignant neoplasms (9.2%). Congenital malformations, diseases of the heart, influenza and pneumonia, and chronic lower respiratory disease such as asthma continue to be major contributing factors in pediatric death. While death rates for unintentional injuries, homicides, heart and cerebrovascular disease have decreased between 2010 and 2011, death rates from suicide continue to climb.

Sudden unexpected infant death (SUID), defined as deaths in infants younger than 1 year of age that occur suddenly and without

any obvious cause prior to extensive investigation, are often encountered by emergency physicians (2). Most infant and child deaths are pronounced in the ED, even if the death occurred in the prehospital setting. SUID claims the lives of approximately 4,000 infants each year in the United States, half of these are due to SIDS (2). The emergency physician should be knowledgeable about the epidemiology and differential diagnosis of SIDS. SIDS is defined as the sudden death of an infant younger than 1 year of age that remains unexplained after thorough case investigation, including performance of a complete autopsy, examination of the death scene, and a review of the clinical history. Most deaths due to SIDS occur between 2 and 4 months of age. Understanding of the etiology of SIDS remains incomplete, despite extensive research in this area (3–5).

SIDS is the third leading cause of infant mortality in the United States and has important implications in pediatric death (2). The rate of SIDS is two to three times more likely in African American and Native American populations. SIDS has been associated with prone sleep position, sleeping on a soft surface, maternal smoking during or after pregnancy, overheating from heavy bedding or clothing, late or no prenatal care, young maternal age, prematurity, LBW, and male gender (2–5). Many states have death review teams for unexplained infant deaths. Deaths caused by carbon monoxide poisoning, asphyxia in mechanically unsafe sleeping environments, and overlying (smothering) are often initially labeled as SIDS until investigation and/or autopsy confirms an alternate diagnosis. SIDS deaths had been slowing declining in the United States during the 1980s until the American Academy of Pediatrics Back to Sleep campaign took off in 1992. Since that time, the SIDS rate has dropped by approximately 50% and continues to decline (2–5). Medical reporting practices have also contributed to the decrease in reported death rates for SIDS, as physicians have begun to use other terms that result in classification of these deaths into the category of “ill-defined or undetermined” causes (1,5). Despite the infant sleep practice changes and improvements in diagnostic and reporting practices, SIDS remains one of the most common reported causes of

death in infants. Emergency physicians should be knowledgeable of the changing epidemiology of pediatric deaths so they can best meet the needs of patients, their families, and hospital staff.

ED EVALUATION

The ED evaluation of a critically ill or injured infant or child begins at transfer of care from the parent or emergency medical services (EMS) and continues throughout the resuscitative efforts and even after death is pronounced. Chapters 214–219, review the specific resuscitative care of children who present to the ED.

The ED physician must be cognizant of details in the medical history or physical examination that would assist in the explanation of the death. A comprehensive history is often not obtained until after death is pronounced, when caregivers are in a state of distress and/or shock. The ED team should make every effort to coordinate history-taking with law enforcement and other agencies. Many larger communities have infant-death scene investigation protocols or teams in place. Information about the scene, including details about bedding, clothing, play equipment, stairs, swimming pools, and other pertinent information may be obtained from EMS providers. For infant deaths, the history should include details regarding recent illnesses, immunizations, medications, feeding, chronic illnesses, and birth history. Family history of neonatal and stillborn deaths, and sudden or unexplained child deaths should be explored (3–8).

The physical examination of infants and children who present with sudden unexplained death or cardiopulmonary arrest should include a search for signs of abuse, metabolic disorders, and congenital syndromes. Presenting signs and symptoms of child abuse may often mimic other medical illnesses and accidental traumatic injuries. Frequency estimates of nonaccidental death that is incorrectly designated as SIDS range from 1% to 5% (4). In addition to a complete examination, particular attention should be given to body temperature, skin markings, pupil size, and dysmorphic features (3–5). When SIDS is suspected, inform the family that SIDS is a diagnosis of exclusion and that other investigations are required.

FAMILY-CENTERED CARE DURING RESUSCITATION

Involving family member presence during pediatric resuscitation in EDs has been a focus of quality improvement and a practice formally endorsed by many healthcare organizations (9,10). Parents and guardians serve as the primary support system for pediatric patients and play an integral role in the health and well-being of the child. The practice of family-centered care incorporates family attitudes and beliefs about autonomy and health care into what was previously an autocratic medical model in which families were excluded from the treatment area.

Awareness of the benefits of family presence and support for the incorporation of family-centered care has increased over the past decade. Patients undergoing invasive procedures and those who survived resuscitations have expressed feelings of comfort, reduced anxiety, and better pain management when families were present (11). For family members, being present helps them advocate for their child in real time and share pertinent medical information (17). Even when their children died, parents who were with them at the time of death experienced a greater sense of closure than parents who were prevented from being present (12). Family presence may also have greater long-term benefits for families. A study evaluating family presence during prehospital resuscitation showed lower posttraumatic stress disorder–related symptoms for family members who witnessed the resuscitation efforts compared to those who did not (13).

Family members are often with their children when they present to the ED but it is not uncommon for them to be separated from their children during the initial phases of resuscitation. Staff should be supportive in encouraging family presence during invasive procedures and resuscitative efforts, but cautious not to force family participation. Family members should be given the option to be present during their child's care and supported in their decisions. It is important to provide a private, quiet, and comfortable space when assisting parents with saying goodbye to their child or viewing the body.

PRONOUNCEMENT OF DEATH AND NOTIFICATIONS

Pronouncement of death should be made by the attending physician, or the most senior physician who was in attendance at the time of death. The attending physician should also be the one to notify the parents or legal guardians. If the family is not present at the time of death, they should be requested to come to the hospital where the information of the death should be given. In the event that the parents cannot be contacted, social services should be utilized to help locate family or next-of-kin. Most emergency physicians feel uncomfortable dealing with death and giving bad news to families, and historically they have received little training in this area. Most physicians are not skilled in how to conduct these important and stressful conversations, but it is imperative that they be competent in these situations. Families may not recall the details of the actual event, but the manner with which it was disclosed will have lasting effects. Breaking bad news is a skill that can be learned and has been shown to improve with communication specific education. Simulation scenarios, role playing, and other educational tools that focus on death and delivering bad news have been incorporated into both Pediatric Advanced Life Support (PALS) and Advanced Pediatric Life Support (APLS) courses, and should continue to be part of medical education and training (14,15). A useful educational tool that uses a 'GRIEV_ING' mnemonic has been shown to improve ED physician competence and confidence in death notification skills (Table 293.2) (14).

TABLE 293.2
GRIEV_ING Mnemonic[a]

- *G*ather the family; ensure that all members are present.
- *R*esources; call for support resources available to assist the family with their grief (i.e., chaplain services, ministers, family, and friends).
- *I*dentify; identify yourself, identify the deceased or injured patient by name, and identify the state of knowledge of the family relative to the events of the day.
- *E*ducate; briefly educate the family as to the events that have occurred in the ED; educate them about the current state of their loved one.
- *V*erify; verify that their family member has died. Be clear! Use the words dead or died.
- (*S*pace); give the family personal space and time for an emotional moment; allow the family time to absorb the information.
- *I*nquire; ask if there are any questions, and answer them all.
- *N*uts and bolts; inquire about organ donation, funeral services, and personal belongings. Offer the family the opportunity to view the body.
- *G*ive; give them your card and access information. Offer to answer any questions that may arise later. Always return their call.

[a]Adapted from Knazik SR, Gausche-Hill M, Dietrich AM, et al. The death of a child in the emergency department. *Ann Emerg Med* 2003;42(4): 519–529, used with permission.

After the pronouncement of death and the notification of family, the parents should be invited to the bedside, if not already, to be with their child and hold him/her if possible. In preparation, the body should be cleaned for family viewing. Adherence to strict guidelines may be required during preparation of the body, especially if the case is a Medical Examiner's case. Monitoring equipment may be disconnected and the body bathed as necessary to remove obvious body secretions. All tubes from the body, including endotracheal tubes, IV access devices, Foley catheters, chest tubes, feeding tubes, etc. should not be removed. Tubes and IVs may be capped to prevent body fluid from leaking and visible wounds may be covered for viewing.

When a child dies in the ED, the attending physician or designee should notify the child's primary care physician, the Medical Examiner's Office, and the regional organ transplant organization. The licensed independent physician (LIP) in attendance at the time of death is often responsible for completing the Death Worksheet at most institutions. All death packet worksheets and documentations should be completed immediately after the death and prior to

transport of the body to the morgue. In Medical Examiner cases, the death certificates are completed by the Medical Examiner. Social work or international services should be also be utilized in cases where patients with religious beliefs require an expedited death certificate.

AUTOPSY AND ORGAN DONATION

ED staff should be aware of state and local requirements for reporting deaths and for organ donation. The physician pronouncing death is often responsible for determining whether or not the death is a Medical Examiner's case, and if so, has the responsibility of notifying the Medical Examiner's Office immediately after the death. If there are questions as to whether or not the circumstances of death meet the definition for a Medical Examiner's case, the local Office of the Chief Medical Examiner should be contacted and consultation obtained.

Postmortem examinations by state medical examiners are often required in all sudden, unexpected, and unexplained deaths not caused by readily recognizable disease. The definition of reportable deaths varies among states and jurisdictions of medical examiners but also usually includes violent causes of death (homicide, suicide, accidents); deaths which might constitute a threat to public health; deaths of persons whose bodies are to be cremated; deaths related to medical or surgical intervention; and deaths under suspicious circumstances. Consent for autopsy must be obtained prior to autopsy for all deaths except for Medical Examiner's cases. Who can give consent for autopsy may vary by state law, but often includes the nearest blood relative (parents) or legal guardians.

Parents should be made aware of the importance of understanding why their child died and whether other or future children might be affected. Autopsies in infant deaths are strongly encouraged to find evidence of familial genetic disease, infection, public health threats, or child abuse and neglect. Genetic disease is a major contributing factor in 15% to 25% of all infant deaths, with more than 400 inborn errors of metabolism having now been identified (16). Autopsy results should be made available to the parents, and it should be

conveyed to them that a final report may require several months to prepare. Postmortem examinations have been shown to alter recurrence risks for future pregnancies by 25%, making neonatal and infant autopsies of crucial importance (16).

The attending physician or designee is responsible for notifying the local or regional transplant organization after the death of a patient and is recommended to do so within 1 hour of the death regardless of organ donation suitability. Organ donations have made more than 28,000 transplants possible and have given another 1 million people tissue transplants that have helped them recover from trauma, spinal injuries, bone damage, burns, and hearing and vision loss (17). An experienced interdisciplinary team should be utilized to help identify potential organ donors and preserve the donation for families in cases where donation is a viable option. Families should be informed of the option of organ donation and the involvement of a specialized team only after the declaration of death has been made. An experienced team from an organ transplant organization will then help determine the suitability of organs for donation and discuss the option with the family in a manner that is considerate of cultural, ethical, and religious practices.

GRIEF REACTIONS

Society often reacts to pediatric death or terminal illness with disbelief, helplessness, and often anger. Cultural and religious background should be taken into consideration when responding to a parent's grief. Physicians should be knowledgeable of local and common cultural and religious beliefs and respect these traditions (Table 293.3) (7,8).

TABLE 293.3
Common Burial Traditions

Religion	Death Practices
Buddhism	The body is left as it is found in death and gently covered with a sheet.
Catholicism	Before or after the time of death, a priest should administer the sacrament of anointing the sick.
Hinduism	Death should be peaceful, and the body must be attended until cremation.
Islam	After the death, the eyes are closed, the mouth is closed with a bandage, and the arms and legs are straightened.
Judaism	The burial is arranged within 24 hours. The body must be attended until the burial. Cremation is not acceptable.

Extreme sadness, anxiety, guilt, disbelief, and anger can be normal reactions to the death of a child. Parents and family members may express prolonged feelings of guilt, especially if the death was a result of accidental injury. Family members may exhibit emotional lability and blame one another if the death was associated with inadequate supervision. Hostility among family members may be increased in cases of divorced or separated parents. Infants and children may also have had a recent primary care visit before a sudden death occurs, and parents may express anger at the last physician who treated the child. Parents may ask the emergency physician why or how there could have been a delay or failure in the diagnosis by their child's primary care physician.

SUPPORT AND COUNSELING

Interventions for helping survivors cope with grief are reviewed in Chapter 169: Bereavement and Grief Reactions. The grieving parent or family member must be supported during the event of breaking the tragic news and during months after their loss by social services and bereavement resources. EDs should have bereavement guidelines in place, including a death plan addressing notification of family, burial arrangements, organ donation, advance directives, autopsy requests, and family support. Although many national resources and protocols for pediatric ED deaths exist, each case must be individually addressed with local or state statutes followed. An example of an ED death protocol is shown in Figure 293.1. An

example of practice guidelines developed by a multidisciplinary panel for coping with death in the ED setting is summarized in Table 293.4 (15). Family support services should provide trained and skilled bereavement counseling, coping assessment, and referral services offered through an interdisciplinary program that protects and respects the religious, cultural, spiritual, psychological, and ethical needs of all family members. The support team may include physicians, nursing staff, social workers, chaplains, the primary care physician, and other local support groups (6). Institutions can also assist families through this event with formal programs that provide follow-up to all families for a designated period of time, Memory Boxes with hand or foot prints, grief support literature and resources for siblings, and consultation to individuals or organizations in the wider community who experience childhood death. National support organizations are listed in Table 293.5.

PROCEDURE: Pediatric Death In The ED
Support For Survivors

Physician Responsibilities

1. Notify chaplain early, as soon as death appears inevitable. Ask clerk or nurse to page chaplain via operator
2. Talk with family (listen!)
   - Intervene early and report progress
   - Answer specific questions to the best of your ability
   - Assure the family that medical care was complete
   - Allay parental guilt
   - Take PA/Nursing staff with you
   - *Remember:* Doing nothing is doing something! Some people just cannot be consoled or reached acutely
3. Allow family to view or hold their child.

Nursing Responsibilities

1. Assign consistent nurse to the family
2. Facilitate ED phase
3. Accompany physician and chaplain
4. Provide a quiet room and rocking chair
5. Complete ED checklist
6. Personally ensure paperwork forwarded to ED Nurse Manager's office
7. Attach letter requesting medical examiner's report to Notice of Death worksheet

Follow-Up Phase

1. Chaplain phone call to parents 1-2 weeks after death to coordinate support group participation
2. Patient relations to coordinate physician/survivor meeting to review autopsy findings or answer questions

Checklist for Pediatric Deaths

Patient name_____Unit #_____Date_____

Relative name_____Address_____

Phone #_____Account #_____

Initial Emergency Department Phase

____ Staff person assigned to family members, who?
____ Ask family if patient has had a primary physican or medical clinic
____ If so, who?
____ Medical examiner notifed
____ Family notification of death and tentative cause (essential family members present in emergency department)
____ Family permitted to see baby/tangible evidence of death offered (eg, lock of hair), special requests honored, if so, what? _____
____ Family allowed to express grief; respond to individual needs
____ Family members understand how they may receive autopsy report
____ Family informed of follow-up procedures and given a phone number to call if they have questions
____ ED chart completed (including ED form)
____ Copy of chart enclosed
____ Organ donation

EMS Office Phase

Family physician/clinic notified of death on_____Phone #_____by_____

Copy of checklist retained in EMS office? _____Yes _____No

Comments_____

Chaplain's Phase

FIGURE 293.1 Example of ED death protocol.

TABLE 293.4
Bereavement Practice Guidelines for Healthcare Professionals in the ED[a]

Phase One

Preparing the ED to Help the Family of a Critically Ill or Injured Child Who Dies

- Have protocols and procedures in place (media, police, ME, family presence, death certificate, organ donation)
- Train all the ED staff (physicians, nurses, techs, students, clerks, and security) about the needs of families, including expected reactions, and cultural and religious differences
- Designate a family room with a phone
- Assign a trained FCP, chaplain, or other appropriate staff to work with the family

Phase Two

When the Critically Ill or Injured Child and the Family Arrive in the ED

- FCP should prepare for the arrival of the family if time permits
- FCP should greet the family upon arrival to the ED
- FCP guides family to a private room
- FCP is the liaison between family and staff and remains with family for duration of stay

Phase Three

When a Child Dies in the ED

- Help the family with grief expressions: anger, sadness, fainting, violence, and guilt
- Review all procedures and "what was done" to help their child
- Praise family and allay guilt
- Explain role of ME, autopsy, organ or tissue donation, law enforcement, child abuse and other agencies
- Contact family's religious or spiritual leader
- Give family option of spending time with their deceased child if allowed by law enforcement or medical examiner
- If appropriate, offer funeral resources
- Offer informational and resource brochures to take home

Phase Four

Follow-up After the Death of a Child in the ED

- Follow-up plan
- Letter of condolence
- Meeting to review autopsy or ME results
- Time for questions
- List of bereavement support groups
- Most hospice programs and children's hospitals offer programs and support

Phase Five

Helping Staff Cope with Childhood Deaths

- Proper education and supervision
- Debriefing sessions in some cases
- Recognize outstanding work

ED, emergency department; ME, medical examiner; FCP, family care provider.

65 Nielson St, #108
Watsonville, CA 95076
Ph: (831)763-3070

SIBLING AND CHILDHOOD BEREAVEMENT

The emergency physician should also be knowledgeable about the grieving process in surviving children. The American Academy of Pediatrics recommends addressing the following questions: What is death? What made the person die? Where is the person? Can it happen to me? Who will take care of me? Table 293.6 lists manifestations of grief in children by age and developmental level.

The child's pediatrician or primary care physician should be involved in monitoring the grief process (18).

TABLE 293.6
Manifestations of Grief in Children

Young Children (<3 yrs of age)	Preschool Children	School-Age Children	Adolescents
Regression sadness	Increased activity	Deterioration of school performance caused by loss of concentration, disinterest, lack of motivation, failure to complete assignments, and day dreaming in class	Depression
Fearfulness	Constipation	Resistance to attending school	Somatic complaints
Anorexia	Encopresis	Crying spells	Delinquent behavior
Failure to thrive	Enuresis	Lying	Promiscuity
Sleep disturbance	Anger and temper tantrums	Stealing	Suicide attempts
Social withdrawal	"Out-of-control" behavior	Nervousness	Dropping out of school
Developmental delay	Nightmares	Abdominal pain	
Irritability	Crying spells	Headaches	
Excessive crying		Listlessness	
Increased dependency		Fatigue	
Loss of speech

ED PHYSICIAN AND STAFF CONCERNS

Medical resuscitations in the ED require teams to perform under a tremendous amount of pressure, and when poor outcomes or unexpected deaths occur, the stress on providers can become overwhelming. Emergency physicians on average experience a mean of approximately 17 patient deaths per year and are exposed to a much higher death rate than many other subspecialties (19). Pediatric deaths are rare, but depending on the surrounding demographics and subspecialty certification of an ED, emergency staff may be exposed to significantly higher rates of pediatric deaths. Following failed resuscitations of critically ill patients, providers have reported intense feelings of guilt or inadequacy and considerations of alternative professions (6,19). Pediatric deaths are particularly stressful for staff members. Staff should be observed for signs of depression, hostility, burnout, or substance abuse. A crisis intervention team should be considered if an unusual number of pediatric deaths occur or if a mass-casualty incident exposes the staff to many deaths at one time. Death policies and crisis counseling skills should be part of the orientation program for new ED staff members.

Team debriefing after resuscitation is one intervention that has been shown to mitigate stress by fostering an opportunity for reflection and emotional processing (20,21). Debriefing allows healthcare teams to reexamine the clinical event and discuss individual and team performance, identify errors, and develop plans for performance improvement. The facilitated discussion format of medical debriefings promotes a sense of shared responsibility, builds team trust and morale, and helps with future practice improvements (20,22). Given the infrequent occurrence of pediatric resuscitations, emergency teams would benefit from debriefing practice using simulation. Research shows debriefing to be a skill that improves with practice and one that is influenced positively by the use of Debriefing Tools to facilitate the discussion (21,22). The American Heart Association, American Academy of Pediatrics, and the European Resuscitation Council all recommend routine use of debriefing in clinical practice to improve performance (23–24).

Common Pitfalls

- Assuming unexplained infant deaths are caused by SIDS without looking for signs of abuse, underlying illness, congenital disorders, or sepsis.
- Failure to have an organized plan or protocol for childhood deaths in the ED.
- Failure to contact the patient's primary-care or subspecialty physician.
- Failure to attend to grief reactions in parents and siblings.
- Failure to recognize the benefits of debriefing after resuscitation for ED staff.

CHAPTER 294

Consent for Care of Children, Adolescents, and Emancipated Minors

Samantha L. Rosman

In the United States, with a few exceptions that will be noted, minors (defined as under age 18 in most states) are unable to consent to their own medical care and require a surrogate such as a parent or guardian to consent on their behalf (1). While the majority of children are brought into the emergency department (ED) by their parents and consent is easily obtained, emergency physicians regularly encounter children brought in by an adult who is not a parent or legal guardian, or adolescents who are seeking care on their own. In these situations physicians must decide what care can and should be provided immediately and what care should be withheld until appropriate consent can be obtained.

UNACCOMPANIED MINORS

The American College of Emergency Physicians (ACEP) states in its policy on the treatment of minors that "the evaluation and necessary treatment of a minor in the ED should not be delayed because of consent issues" (2). Indeed, under the federal Emergency Medical Treatment and Active Labor Act (EMTALA), any hospital that receives federal funding for any of its programs must perform an initial medical screening examination (MSE) for every patient seeking treatment. This examination is required regardless of the

patient's ability to pay or the availability of consent for treatment. The screening must determine whether an emergency medical condition exists, defined as life- or limb-threatening, severe pain, or conditions with potential for serious impairment or dysfunction if left untreated (3). A MSE may be as simple as a physician's examination in triage or may require extensive laboratory testing, imaging, and subspecialty consultation to rule out an emergency medical condition. The ACEP policy also states that an emergency is not only a condition that can cause death or disability but may also include urgent conditions that, if not treated immediately, may result in further complications, pain, fever, disease transmission, etc. (2). Consequently, if the parents of a child with an uncomplicated forearm fracture cannot be reached in a timely manner, physicians can in most cases act in the child's best interest to reduce and splint the fracture if it will decrease the risk of future complications. The understanding is that a reasonable parent or guardian would consent to emergency care if able to do so. In other words, under these circumstances physicians may act with "implied consent" and invoke the emergency exception rule to parental consent for treatment of an unaccompanied minor (Table 294.1) (1).

TABLE 294.1
Conditions of Emergency Exception Rule

1. Child's life or health is in danger as a result of the emergency condition;
2. Child's legal guardian is unavailable or unable to provide consent;
3. Treatment cannot be safely delayed until consent is obtained; AND
4. Treatment is administered only for emergent conditions that pose an immediate threat to the child.

Data from Committee on Pediatric Emergency Medicine and Committee on Bioethics. Consent for emergency medical services for children and adolescents. *Pediatrics*. 2011;128;427–433;Tsai AK, Schafermeyer RW, Kalifon D, et al. Evaluation and treatment on minors: Reference on consent. *Ann Emerg Med*. 1993;22:1211–1217.

If the emergency exception rule is invoked, the following should be clearly documented in the chart: (1) The emergent nature of the condition, (2) the reason immediate care was required, and (3) the unsuccessful efforts made to obtain consent. Courts are almost

universally supportive of physicians in these situations if they are perceived as acting in the child's best interest (1).

ADOLESCENT CONSENT ISSUES

Many adolescents seen in the ED remain minors in the eyes of the law and thus require parental consent for treatment. There are several situations, however, in which the law allows adolescents to consent for themselves (Table 294.2).

TABLE 294.2
Adolescent "Minors" Able to Consent for Themselves

1. Emancipated minor;
2. Specific medical condition exception; OR
3. Mature minor exception.

Data from Committee on Pediatric Emergency Medicine and Committee on Bioethics. Consent for emergency medical services for children and adolescents. *Pediatrics*. 2011;128:427–433;Tsai AK, Schafermeyer RW, Kalifon D, et al. Evaluation and treatment on minors: Reference on consent. *Ann Emerg Med*. 1993;22:1211–1217; Holder AR. Minors' rights to consent to medical care. *JAMA*. 1987;257:3400–3402.

Emancipated minor laws vary by state, and it is important to be familiar with the particular laws that apply. Minors are often defined to be "emancipated" when they (1) are legally married, (2) are economically self-sufficient and not living with parents or guardians, (3) are on active duty military, or (4) are pregnant or a parent themselves. Some states require a court to legally declare a minor emancipated rather than allowing circumstances alone to define the minor's status (1,2,4).

Most states allow minors to consent on their own for care for specific medical conditions such as drug or alcohol abuse, mental health issues, sexually transmitted infection testing and treatment, or pregnancy-related issues (1,4). The specific situations vary as to where, and the ages at which, minor consent is allowed for these or similar conditions.

Most states also provide for a mature minor exception. Although in some jurisdictions the court must declare such an exception, the

physician is empowered to make the decision in others. A mature minor is generally an adolescent—age 14 or older—with the maturity and capacity to understand the risks and benefits of a proposed treatment and the ability to make a reasonable decision after considering the information given. Generally, in cases where the physician is empowered to decide whether the minor is mature, the treatment must (1) be to the minor's benefit, (2) be acutely necessary, and (3) not involve serious risks (1,4).

ADOLESCENT CONFIDENTIALITY

Confidentiality from parents is often a very important issue for adolescents seeking care of their own accord. On the federal level, The Health Insurance Portability and Accountability Act (HIPAA) Privacy Rule protects the confidentiality of personal health information from disclosure to third parties. Under HIPAA, however, parents or guardians are considered representatives for their minor children and thus generally have access to their children's health information. There are two major exceptions. First, a parent can agree to a confidential relationship between the physician and the adolescent, thereby transferring the right of disclosure to the minor. Second, the parent can lose the right to the minor's health information in cases in which the state law does not require parental consent for treatment (5,6).

Except for information protected from disclosure by the federal Family Planning Act (FPA), the issue of parental access to a minor's health information is not otherwise covered by federal law (1). Consequently, adolescent consent issues are governed by state law. Some states explicitly require parental notification—depending on the circumstances—while others specifically guarantee confidentiality in cases that permit adolescent consent. Once again, it is critical for physicians to be familiar with applicable parental disclosure and confidentiality laws in the jurisdictions in which they practice.

Physician must be honest and candid with their adolescent patients as to what can be kept confidential and what cannot (see

Chapter 289). In most states, parents have a legal right to request their minor child's medical record unless the parents' possession of the records would put the child in danger or the parent has previously agreed to waive the right to such access. In addition, parents, as the primary insurance holders, often receive bills for services that may disclose diagnoses, procedures, or other aspects of the adolescent's care that may at least partially betray confidentiality. Thus, confidentiality can often only be reliably maintained if the adolescent takes on financial accountability for his or her care, and it is important to identify a confidential way of contacting the patient with the results of pending studies or the need for return visits (1,2).

PARENTAL REFUSAL OF TREATMENT

Parents and guardians generally have the authority to make decisions on behalf of their children and, therefore, to consent to or refuse medical care. In most cases, the parents' decision should be honored, but parental authority is not absolute and is limited by parents' duty to ensure the safety and health of their children. If the parent or guardian acts in such a way that the child's health, well-being or life is in jeopardy, the state may intervene under the doctrine of *parens patriae.* Based on society's obligation to protect its most vulnerable members, this doctrine grants the state the right to act *in loco parentis,* in place of the parent, when it is necessary to protect the life and health of those who cannot take care of themselves, including children (1,2,7,8).

The issue often arises with parents of certain religious groups that are opposed to lifesaving medical interventions. For example, this occurs when Jehovah's Witnesses refuse blood products for their children. In the United States, Jehovah's Witness parents often argue that they have the right to refuse blood on their child's behalf under the Free Exercise Clause of the First Amendment. However, American courts have almost universally ruled in favor of child welfare and have rejected the First Amendment argument in these circumstances. The majority of courts hold that while the freedom

to believe is absolute, the right to practice religion freely does not include the right to put a child at risk of serious illness, injury, or death (8).

Similarly, when the state determines medical neglect, it can act *in loco parentis* and assume temporary custody to authorize medical care if this is being done to protect the "health or safety of the child" (1,8–12).

If a physician believes that a parent's decision places a child's life or health in significant danger, every effort should be made to persuade the parent to consent to the proposed lifesaving treatment. If this is unsuccessful, or the situation does not allow for delay, the physician may need to notify both the police and child protective services and have the child placed in temporary protective custody. In these cases, the doctrine of *parens patriae* allows the state to interfere on behalf of the child's welfare. Such authorization extends only to conditions that are serious or life-threatening (1,2,8).

SUSPECTED CHILD ABUSE AND NEGLECT

In cases where there is suspected child abuse or neglect and the parents refuse to consent to evaluation and treatment, *the physician's primary duty is to protect the child's safety and well-being.* In addition to the mandated reporting of the suspected abuse or neglect, the physician will need to involve state child protective services or local law enforcement to obtain *parens patriae* consent to evaluation and treatment (1,2).

SECTION XXIII
Toxicology

Section Editor: LOUIS J. LING

PART 1 • GENERAL CONSIDERATIONS

CHAPTER 295 Evaluation of the Poisoned Patient

Jerrold B. Leikin

The history and physical examination is the cornerstone of clinical patient management, and while taking a history may be a direct method for toxin exposure identification, quite often it is not reliable. Information obtained may prove minimal in some cases and should be considered partial or inaccurate in suicidal gestures and with illegal drug or chemical use. Thus, obtaining a history of exposure from family, friends, coworkers, or prehospital personnel, may be essential to patient management.

IMMEDIATE CRITICAL INTERVENTION

An immediate decision with regard to stability needs to be made upon patient presentation. Unstable vital signs need to be assessed and addressed in the traditional manner. Supportive measures including the "ABCs" (airway, breathing, circulation) are often required before confirmation of intoxication can be obtained. Intubation is not always necessary when cough and gag reflexes are present and there is adequate spontaneous ventilation; however, when there is a concern regarding airway protection and potential clinical deterioration, it is better to secure the airway. Intubation is indicated in acute respiratory failure. Other specific indications include the need for high levels of supplemental oxygen (e.g., in carbon monoxide poisoning) and the need to protect the airway for gastric emptying or decontamination. Endotracheal intubation

decreases (but does not eliminate) the risk of aspiration (which is approximately 10% in the comatose patient with drug overdose) (1).

The “coma cocktail” (dextrose, oxygen, thiamine, and naloxone) is diagnostic as well as therapeutic, and should be administered empirically to the comatose patient with a suspected toxic exposure (2,3). A rapid bedside blood glucose can determine which patients should receive dextrose, although a low normal value by blood dipstick does not always exclude low serum glucose. The dose is 50 g IV in an adult; 2 to 4 mL/kg body weight of a 25% solution in a child. Thiamine (50 to 100 mg) can treat or avoid Wernicke encephalopathy syndrome, which is particularly important in the nutritionally depleted alcoholic; there is no evidence that dextrose should be withheld until thiamine is administered.

Naloxone rapidly reverses coma, respiratory depression, and hypotension induced by opioids. An initial dose of 0.2 to 0.4 mg in adults is administered IV, subcutaneously, IM, or endotracheally. The intratrachael dosage is diluted to 1 to 2 mL in normal saline. If there is no response, an additional 1 to 2 mg can be repeated. The pediatric dose is 0.1 mg/kg, repeated every 2 to 3 minutes as needed. Use of a higher initial dose may precipitate withdrawal symptoms in opioid-dependent patients. Heroin and morphine are the most sensitive to naloxone, and while some opioid agents such as meperidine, propoxyphene, diphenoxylate, methadone, and pentazocine require larger doses. A lack of response to 10 mg of naloxone generally excludes opioid toxicity (see Chapter 305 for details about naloxone use).

Flumazenil should be considered in cases where benzodiazepine overdose alone is suspected or when reversal of therapeutic conscious sedation is desired. Case reports suggest a risk of precipitating seizures with flumazenil when there is a suspicion of benzodiazepine plus cyclic antidepressant overdose. See Chapter 308 for details on use of flumazenil. The routine use of flumazenil is discouraged, except in cases of acute benzodiazepine overdose presenting as coma or respiratory depression without any coingestants (4).

DIAGNOSTIC APPROACH

A quick and focused physical examination often leads to important clues about the nature of the toxin. These clues can be specific symptom complexes associated with certain toxins and can be referred to as “toxidromes” (Table 295.1) (5).

TABLE 295.1
Common Toxidromes

Toxidrome	Features	Drugs/Toxins
Anticholinergic	Mydriasis	Antihistamines
"Hot as a hare, dry as a bone, red as a beet, mad as a hatter"	Blurred vision	Atropine
		Fever
		Dry skin
	Flushing	Tricyclic antidepressants
	Ileus	Phenothiazines
	Urinary retention	Propantheline
	Tachycardia	Scopolamine
	Hypertension	
	Psychosis	
	Coma	
	Seizures	
	Myoclonus	
Cholinergic "SLUDGE"	*S*alivation	Carbamate
	*L*acrimation	Organophosphates
	*U*rination	Physostigmine
	*D*iarrhea	Pilocarpine
	*G*I cramps	
	*E*mesis	
	Wheezing	
	Diaphoresis	
	Bronchorrhea	
	Bradycardia	
	Miosis (pinpoint pupils)	
β-Adrenergic	Tachycardia	Albuterol
	Hypotension	Caffeine
	Tremor	Terbutaline
		Theophylline
α-Adrenergic	Hypertension	Phenylephrine
	Bradycardia	Phenylpropanolamine
	Mydriasis	
β- and α-Adrenergic	Hypertension	Amphetamines
	Tachycardia	Cocaine
	Mydriasis	Ephedrine
	Diaphoresis	Phencyclidine
	Dry mucous membranes	Pseudoephedrine
Sedative/hypnotic	Stupor and coma	Anticonvulsants
	Confusion	Antipsychotics
	Slurred speech	Barbiturates
	Apnea	Benzodiazepines
		Ethanol
		Meprobamate
		Opiates
Hallucinogenic	Hallucinations	Amphetamines
	Psychosis	Cannabinoids
	Panic	Cocaine
	Fever	Lysergic acid diethylamide/ Indole alkaloid
	Mydriasis	Phencyclidine (may present with miosis)
	Hyperthermia	
	Synesthesia	

Toxidrome	Features	Drugs/Toxins
Extrapyramidal	Rigidity/tremor	Haloperidol
	Opisthotonos	Phenothiazines
	Trismus	Risperidone
	Hyperreflexia	Olanzapine
	Choreoathetosis	
Narcotic	Altered mental status	
	Slow shallow breaths	Opiates
	Miosis	Pentazocine
	Bradycardia	
	Hypotension	
	Hypothermia	
	Decreased bowel sounds	
Serotonin	Irritability	Fluoxetine
	Hyperreflexia	Meperidine
	Flushing	Paroxetine
	Diarrhea	Sertraline
	Diaphoresis	Trazodone
	Fever	Clomipramine
	Trismus	Selective serotonin reuptake inhibitor
	Tremor	Tramadol
	Myoclonus	
Epileptogenic	Hyperthermia	Strychnine
	Hyperreflexia	Nicotine
	Tremors	Lindane
	May mimic stimulant patterns	Lidocaine
		Xanthines
		Isoniazid
		Chlorinated hydrocarbons
		Camphor
Solvent	Lethargy	Hydrocarbons
	Confusion	Acetone
	Headache	Toluene
	Restlessness	Naphthalene
	Incoordination	Trichloroethane
	Derealization	Chlorinated hydrocarbons
	Depersonalization	Petrochemicals
Uncoupling of oxidative phosphorylation	Hyperthermia	Aluminum phosphide
	Tachycardia	
	Metabolic acidosis	Cyanide
		2,4-Dichlorophenol
		Dinitrophenol
		Glyphosate
		Phosphorus
		Pentachlorophenol
		Zinc phosphide

Vital Signs. Depending on the intoxication, patients may present with hypotension or hypertension, bradyarrhythmias, or tachyarrhythmias. The pathogenesis of hypotension varies and may include hypovolemia, myocardial depression, cardiac arrhythmia, or

systemic vasodilation. Treatment should be individualized, but an initial strategy of rapid intravenous normal saline solution infusion is indicated in most instances. Vasopressors may be required for refractory hypotension. The vasopressor of choice depends on the type of intoxication. For example, norepinephrine appears to be advantageous over dopamine in tricyclic antidepressant-induced hypotension (6). Lipid rescue therapy can be considered in the setting of hemodynamic instability—this is discussed further in Chapter 296. Hypertension occurs with sympathomimetic drugs, anticholinergics, ergot derivatives, phenylpropanolamine overdoses, and withdrawal from nicotine, alcohol, and sedatives. The need to treat the hypertension depends on its chronicity and severity of symptoms and the inciting agent. Hypertension-induced (reflex) bradycardia generally should not be treated.

Anticholinergic and sympathomimetic substances increase heart rate, blood pressure, and temperature. This is particularly true for cocaine intoxication, where hyperthermia may be a particularly ominous sign for mortality. Important clinical signs that differentiate sympathomimetic poisoning from anticholinergic intoxication include dry skin and xerostomia along with absent bowel sounds, which usually occur in anticholinergic but not sympathomimetic poisoning. It should be noted that the antipsychotics and antidepressants with the greatest anticholinergic effects include clozapine, thioridazine, and amitriptyline. In contrast, organophosphates, opiates, barbiturates, β-blockers, benzodiazepines, alcohol, and clonidine cause hypothermia, bradycardia, and respiratory depression. Table 295.2 lists various toxins which alter temperature.

TABLE 295.2
Drugs Affecting Temperature

Hypothermia	Hyperthermia
Akee fruit poisoning	Monoamine oxidase inhibitors
Alcohols	Amphetamines
Barbiturates	Anticholinergics
Clonidine	Neuroleptic malignant syndrome
Colchicine	Lysergic acid diethylamide
Cyclic antidepressants	Antihistamines
Hypoglycemic agents	Cocaine
Lithium	Malignant hyperthermia
Opioids	Cyclic antidepressants
Phenothiazines	Drug withdrawal
Tetrodotoxin food poisoning	Phencyclidine
White Chameleon	Phenothiazines
	Salicylates
	Serotonin syndrome
	Tung Nut
	Cathinone
	Dextromethorphan
	Arsenic
	Strychnine
	Pentachlorophenol
	Dinitrophenol
	Adrenergic agents
	Quinine
	Thyroid medications

Sensorium. Determine whether the patient is comatose, stuporous, lethargic, or alert. Table 295.3 lists drugs that can directly affect mental status, while Table 295.4 lists toxic causes of delirium. Poisoned individuals presenting with deep coma (Glasgow Coma Scale under 7) have a mortality rate approximately seven times higher than overall mortality from acute poisoning (7). **Tables 295.5** and **295.6** list clinical signs of worsening of toxin-induced coma and poor prognostic signs of coma. Table 295.7 lists drugs that can cause cyclic or relapsing coma.

TABLE 295.3
Selected Drugs Altering Mental Status

Depressed Physiologic State	Agitated Physiologic State
Sympatholytics	Sympathomimetics
Adrenergic blockers	Adrenergic agonists
Antiarrhythmics	Amphetamines
Antihypertensives	Caffeine
Antipsychotics	Cocaine
Cyclic antidepressants	Ergot alkaloids
Cholinergics	Monoamine oxidase inhibitors
Bethanechol	
Carbamates	Theophylline
Nicotine	Anticholinergics
Organophosphates	Antihistamines
Physostigmine	Antiparkinsonian drugs
Pilocarpine	
Sedative/hypnotics	Antipsychotics
Alcohols	Antispasmotics
Barbiturates	Cyclic antidepressants
Benzodiazepines	Cyclobenzaprine
Gamma hydroxybutyrate	Drug withdrawal
Ethchlorvynol	Clonidine
Narcotics	Ethanol
Analgesics	Opioids
Antidiarrheal agents	Sedative/hypnotics
Other	Hallucinogens

Choline magnesium trisalicylate	Cimetidine	Ciprofloxacin
Clomipramine	Clonidine	Clozapine
Cocaine	Codeine	Colchicine
Cortisone acetate	Cyclobenzaprine	Cycloserine
Cylosporine	Desipramine	Dextroamphetamine
Dibenzepin	Dicyclomine	Digitoxin
Digoxin	Diphenhydramine	Drug withdrawal
Doxepin	Ergotamine	Estazolam
Ethchlorvynol	Ethyl alcohol	Famotidine
Fentanyl	Flumazenil	Flouride
Fluorouracil	Fluoxetine	Fluphenazine
Glutethimide	Heroin	Hydrocodone
Hydrocortisone	Hydromorphone	Hydroquinone
Hydroxyzine	Hyoscyamine	Imipramine
Interferon α-2a	Interferon α-2b	Interferon α-n3
Interferon β-1b	Interferon γ-1b	Ipratropium
Isocarboxazid	Ketamine	Levodopa
Levomethadyl acetate hydrochloride	Levorphanol	Lidocaine
Lithium	Loperamide	Maprotiline
Mefloquine	Meperidine	Mephentermine
Mesoridazine	Methadone	Methamphetamine
Methohexital	Methotrexate	Methyl salicylate
Methyldopa	Metoclopramide	Mianserin
Midazolam	Morphine sulfate	Nalbuphine
Niacin	Nitroprusside	Nizatidine
Nortriptyline	Opium alkaloids (hydrochlorides)	Opium tincture
Oxycodone	Oxymorphone	Para-aminosalicylate sodium
Paraldehyde	Paregoric	Paroxetine
Pentazocine	Pentobarbital	Perphenazine
Phencyclidine	Phenelzine	Phencyclidine
Phenobarbital	Phenylephrine	Phenytoin
Prazepam	Prednisolone	Procarbazine
Prochlorperazine	Promazine	Promethazine
Propoxyphene	Protriptyline	Quinidine
Ranitidine hydrochloride	Rifampin	Salicylate
Salsalate	Scopolamine	Secobarbital
Serotonin syndrome	Sertraline	Sparfloxacin
Stanozolol	Sufentanil	Tacrolimus
Theophylline	Thioridazine	Thiothixene
Tocainide	Tramadol	Tranlcypromine
Trazodone	Triamcinolone	Trifluoperazine
Triflupromazine	Trimethaphan camsylate	Trimipramine
Valacyclovir	Venlafaxine	Vigabatrin
Vinorelbine	Vitamin A	Zolpidem

Nonmedicinal Agents

1-Propanol	Arsenic	Benzene
Bromates	Carbon dioxide	Carbon tetrachloride
DDT	Diethyltoluamide	Ethylene dichloride
Gasoline	Lead	Lysergic acid diethylamide
Mercury	Nerve gases	Nickel carbonyl
Nitrous oxide	Tetrachloroethane	Thallium
Toluene	Triethyltin	

Biologic Agents

Black nightshade	Boxthorn	Cathinone
Chicken soup	Christmas Cherry	Claviceps purpurea
Daphne	Deadly nightshade	Foxglove
Jimson weed	Lantana	Marijuana (Cannabis)
Morning glory	Mushrooms, Toxic	
(Group II) Monomethyl-hydrazines	Mushrooms, Toxic	
(Group III) Cholinergic Mushrooms, Toxic	Mushrooms Toxic	Oleander
(Group V) Anticholinergic	(Group VI) Psychedelic	
Pennyroyal Oil	Potato (Leaves, stems, tubercles)	Sand Brier
Scorpion fish	Stonefish	Turkey fish
Woody Nightshade	Wormwood	

TABLE 295.5
Neurologic Signs of Worsening of Toxic Coma

Loss of spontaneous blinking or induced blink response
Loss of corneal reflex
Loss of cough or swallow reflex
Flexor toe pattern response to plantar stimulation (Babinski sign)
Decerebrate or decorticate rigidity
Apneustic breathing pattern
Autonomic dysfunction

Behavior and Hallucinations. Often the patient's hallucinatory pattern can be specific for certain drugs. For example, with atropine the patient experiences lilliputian hallucinations; with cocaine, there is a simple visual hallucinatory pattern with objects appearing in the periphery of vision; with phencyclidine, complex hallucinations are often indistinguishable clinically from a paranoid psychosis; with LSD, the patient experiences a combination of illusions, hallucinations, synesthesia, and pseudohallucinations.

Motor Signs. Tremors, hypo- and hyperreflexes, and even the nature of seizures can be useful diagnostic tools. Like hallucinations, seizures caused by specific toxins can exhibit certain specific properties. For example, strychnine is unique in that it can cause generalized seizures while the patient is alert, often called a "spinal

seizure." Most toxin-induced seizures (including withdrawal seizures) will respond to benzodiazepines, barbiturates, or propofol. Other drug-induced seizures respond only to specific antidotal therapies and not conventional antiseizure medication. Examples include anticholinergic-induced seizures, which respond to physostigmine, and isoniazid-induced seizures, which respond to pyridoxine. Most drug-induced seizures rarely respond to phenytoin and may require multidrug therapy. Toxins resulting in isolated cranial neuropathies are rare and are listed in Table 295.8.

TABLE 295.8
Agents Causing Cranial Nerve Palsies

Aldicarb	Arizona Bark Scorpion	Botulinum Toxin Type A
Bromophos	Carbaryl	Carbon disulfide
Chlorfenvinphos	Clostridium botulinum food poisoning	Coumaphos
Demeton-S-methyl	Dichlorvos	Dicrotophos
Didanosine	Dioxathion	Disulfoton
Ethion	Ethylene glycol	Fensulfothion
Fenthion	Ketoprofen	King Cobra envenomation
Lead	Malathion	Mercury
Methidathion	Methiocarb	Methomyl
Methotrexate	Mevinphos	Parathion
Phosdrin	Pravastatin	Profenofos
Propoxur	Rabies virus	Terbufos
Tetraethyl pyrophosphate	Toluene	Trichinella spiralis food poisoning
Trichloroethylene	Vincristine

Ocular Findings. These can be divided into two categories: pupillary size and reactivity, and demonstration of nystagmus.

Pupillary Signs. Both atropine and cocaine can result in mydriasis, but in cocaine or other adrenergic intoxication the pupils respond to light, whereas with anticholinergics the pupils will not respond. Agents that contribute to miosis include organophosphate

insecticides, narcotics, bromide, clonidine, and nicotine. Phencyclidine has been known to cause either mydriasis or miosis. It should be noted that pontine hemorrhage can result in miosis; Drug withdrawal and serotonin syndrome can cause mydriasis (see **Tables 295.9** and **295.10**).

TABLE 295.9
Agents Causing Miosis

Medicinals		
Alfentanil	Bethanechol	Bunazosin
Buprenorphine	Buspirone	Chloral hydrate
Clonidine	Codeine	Dextromethorphan
Edrophonium	Fentanyl	Guanabenz
Guanidine	Heroin	Hydromorphone
Levomethadyl acetate hydrochloride	Levorphanol	Lidocaine
Loperamide	Meprobamate	Meptazinol
Mathadone	Methyprylon	Morphine sulfate
Nalbuphine	Neostigmine	Nilutamide
Opium alkaloids (hydrochlorides)	Opium tincture	Oxycodone
Oxymorphone	Paregoric	Pentazocine
Phencyclidine	Phenobarbital	Physostigmine
Pilocarpine	Procane	Propoxyphene
Pyridostigmine	Rauvolfia serpentina	Reserpine
Tilidine	Tramadol	Valproic acid and derivatives
Zolpidem

Nystagmus. Alcohols are probably the most common etiology of horizontal nystagmus, although lithium, carbamazepine, solvents, meprobamate, quinine, and primidone can also cause horizontal nystagmus. Though phencyclidine classically causes a combination of vertical, horizontal, and even rotary nystagmus, these can also occur with phenytoin and sedative–hypnotics.

In addition to these physical signs, odors emanating from the patient may also provide important diagnostic clues. For example, a garlic odor is often caused by arsenicals, phosphorus compounds, organophosphates, and insecticides.

Laboratory evaluation. The clinical laboratory evaluation includes the evaluation of the "three laboratory gaps of toxicology": anion gap, osmolal gap, and oxygen saturation gap. What these "gaps" have in common is that a substance is accounting for a difference between the calculated and measured determinations.

The anion gap reflects the difference between the serum or plasma measured cation and anion concentrations and is usually calculated utilizing the following formula: Anion Gap = measured Na^+ concentration – [measure chloride and bicarbonate concentrations] (8). The normal range of anion gap is usually 8 to 12 mEq/L in most

laboratories. An increase in anion gap (>16 mEq/L) suggests lactic acidemia, uremia, ketoacidemia, or selected intoxications (see **Tables 295.11** and **295.12**). A normal anion gap does not preclude intoxication because most toxins do not elevate the anion gap or there may be a coexisting condition that lowers the gap. Common among these conditions is hypoalbuminemia: for every 1 g/L decrease in the plasma albumin, the anion gap falls by 2.5 mEq/L. Clinicians should pay special attention to this correction factor to avoid missing a clinically significant anion gap. Also, in methanol or ethylene glycol poisoning, concurrent ethanol use delays the development of an elevated anion gap metabolic acidosis. In this case, an elevated osmolal gap may be the only early clue to the diagnosis.

TABLE 295.11
Common Causes of Abnormal Anion Gap

Elevated Anion Gap	Decreased Anion Gap
Lactic acidosis (type A)	Increased unmeasured cation
Uremia	Hyperkalemia
Sepsis	Hypercalcemia
Rhabdomyolysis	Hypermagnesemia
Ketoacidosis	Acute lithium intoxication
Diabetic	Elevated IgG (myeloma; cationic paraprotein)
Alcoholic	Decreased unmeasured anion
Starvation	Hypoalbuminemia
Toxic ingestions (See **Table 295.12**)	Drugs
	Bromide
	Iodide
Metabolic alkalosis with volume depletion	Lithium
	Polymyxin B
Anion gap without acidosis: Carbenicillin	Analytical artifact
	Hypernatremia (>170 mEq/L)
	Hyperlipidemia

Adapted from Mokhlesi B, Leikin JB, Murray P, Corbridge TC. Adult toxicology. *Critical Care Chest*. 2003;123:577–592.

TABLE 295.12
Selected Drugs Associated with an Elevated Anion Gap Metabolic Acidosis

2-Butoxyethanol	Acetaminophen (>75 g)
Amiloride	Ascorbic acid
Carbon monoxide	Chloramphenicol
Colchicine	Cyanide
Dapsone	Dinitrophenol
Epinephrine	Ethanol
Ethyl acetate	Ethylene glycol
Formaldehyde	Fructose (IV)
Hydrogen sulfide	Ibuprofen (over 400 mg/kg)
Iron	Isoniazid
Ketamine	Linezolid
Metformin	Methanol
Nalidixic acid	Niacin
Nitroprusside	Nitroprusside
Nonsteroidal anti-inflammatory drugs	Papaverine
Paraldehyde	Pennyroyal oil
Pentachlorophenol	Phenelzine
Phenylbutazone	Propofol
Propylene glycol	Salicylates
Sodium azide	Sorbitol (intravenous)
Strychnine	Terbutaline
Tetracycline (outdated)	Toluene (hippuric acid)
Tranylcypromine	Vacor
Verapamil	Zinc phosphide

Adapted from Mokhlesi B, Leikin JB, Murray P, Corbridge TC. Adult toxicology. *Critical Care Chest*. 2003;123:577–592.

Low–molecular-weight drugs and toxins that are osmotically active can increase the discrepancy between measured and calculated plasma osmolality (9). Normal plasma osmolality is 285 to 295 mOsm. The calculated value is determined as follows:

$$\text{Calculated osmolality} = 2[Na^+] + \text{BUN}/2.8 + \text{glucose}/18 + \text{ethanol}/4.25$$

in which Na^+ (in milliequivalents per liter) is multiplied by 2 to account for accompanying anions (chloride and bicarbonate), and

measured BUN, glucose, and ethanol (in milligrams per deciliter) is divided by the appropriate denominator. The osmolal gap must be interpreted with caution. Measurement of osmolality by vapor pressure osmometry does not detect volatile alcohols such as ethanol and methanol; however, it does detect ethylene glycol (10). Freezing point depression osmometry, the most frequently used method, measures all of these solutes. Therefore, it is important for clinicians to know the method used by their institution. With the standard formula, the normal osmolal gap is large and may range from −9 to +5 mOsm; 10 mOsm is considered the upper limit of normal. However, an osmolal gap of 10 mOsm in a patient who started at −9 mOsm may be significantly elevated and the gap may be missed. Table 295.13 lists agents that can cause an osmolal gap.

TABLE 295.13
Causes of Osmol Gap (>10 mOsm from Baseline Values)

I. Exogenous Causes
Dimethyl Sulfoxide[a]
Ethanol[b]
Ethylene glycol
Glycerol[a]
Glycine[a]
Hypermagnesemia (serum level greater than 9.5 mEq/L)
Iodine (questionable)
Isopropyl alcohol (acetone)
Mannitol
Methanol[b]
Osmotic contrast dyes
Sorbitol[a]
Valproic acid
II. Artificial (Blood Collection Tube)
Lavender top (EDTA)—15 mOsm/L
Gray top (sodium fluoride and potassium oxalate)—150 mOsm/L
Blue top (citrate)—10 mOsm/L
Green top (lithium, heparin)—6 mOsm/L

[a]Through intravenous administration.
[b]Also usually results in an associated anion gap metabolic acidosis.
Values are reported as calculated contributions.

An oxygen saturation gap is present when there is more than a 5% difference between the saturation calculated from an arterial blood gas and the saturation actually measured by co-oximetry. Co-oximetry detects the absorption of four different wavelengths, enabling it to directly measure levels of four types of hemoglobin species: oxyhemoglobin, reduced hemoglobin, carboxyhemoglobin, and methemoglobin. Because arterial blood gas analysis calculates oxygen saturation from the measured pO_2 using a standard oxygen–hemoglobin dissociation curve, an oxygen saturation gap occurs in the presence of carboxyhemoglobin, methemoglobin, and sulfhemoglobin (which is not routinely measured by co-oximetry). Pulse oximetry estimates oxygen saturation by emitting a red light (wavelength of 660 nm) absorbed mainly by reduced hemoglobin, and a near-infrared light (wavelength of 940 nm) absorbed by oxyhemoglobin.

Methemoglobin absorbs almost equally at both these wavelengths. At high methemoglobin levels (over 35%), the oxygen saturation by pulse oximetry tends to regress toward 85% and plateaus at that level despite further increments in methemoglobin levels. Thus, if the actual oxygen saturation by co-oximetry is >85%, pulse oximetry underestimates it; if it is <85% by co-oximetry, it overestimates oxygen saturation. A listing of drugs/toxins causing methemoglobinemia is in Table 295.14 (11,12).

TABLE 295.14
Selected Drugs/Toxins Associated with Acquired Methemoglobinemia

Acetanilide	Nitric oxide
Aluminum phosphide (phosphine)	Nitroethane
Amyl nitrite	Nitrobenzene
Butyl nitrite	Nitroglycerin
Bromates	Nitroprusside
Aniline dyes	Pesticides
Benzocaine	Petrol octane booster
Bupivacaine	Phenacetin
Chlorates	Phenazopyridine
Chloroquine	Potassium ferricyanide
Dapsone	Prilocaine
Flutamide	Primaquine
Herbicides	Pyridium Plus (Warner Chilcott, Inc. Rockaway, NJ)
Isobutyl nitrite	Silver nitrate
Isosorbide dinitrate	Sodium chloride
Lidocaine	Sodium nitrite
Loxosceles gaucho venom	Sulfonamides
Methyl nitrite	
Metoclopramide	

Adapted from Leikin JB. Observation unit toxicology. Chapter 19. In: Graff L, ed. The Textbook of Observation Medicine: The Healthcare System's Tincture of Time. Dallas, TX: American College of Emergency Physicians; 2010.

Since many laboratories do not routinely use co-oximetry, a more commonly seen gap is the disparity between measured oxygen saturation by blood gas and that measured by pulse oximetry. Carbon monoxide has a wavelength absorption coefficient similar to that of oxyhemoglobin and carboxyhemoglobin may be misinterpreted as oxyhemoglobin by pulse oximetry, leading to overestimation of oxygen saturation when compared to co-oximetry. Abnormally high venous oxygen content (arterialization of venous blood) is characteristic of cyanide poisoning.

In spite of providing indirect laboratory evidence of intoxication, urine drug screening tests alter management in less than 5% of cases (13). However, toxicology urine drug screening can identify a specific toxin for which an antidote is available and in some instances quantify a toxin allowing for titrated therapy. Most institutions offer urine immunoassay–based testing for six or seven of the most commonly abused drugs. Table 295.15 lists substances that

can give a false-positive urine drug screen (14,15). Results are generally available in 60 minutes. Urine confirmation with gas chromatography/mass spectrometry can usually be obtained, but frequently take an additional 2 to 3 days. Because of false positives, while mean immunoassay confirmation rates are highest for cocaine (98%) and marijuana (91%), the confirmation rate for amphetamine is only about 50% (16); in addition, the presence of a drug on a screening test does not necessarily confirm that the symptoms are from that drug. Many drugs cause a positive urine drug screen for many days. Cocaine metabolites can be seen for up to 5 days, and marijuana can be detected for up to a month. Probably the most important prognostic function for immunoassay urine drug screening is in the patient with occult barbiturate use to ascertain the potential risk for barbiturate withdrawal. More comprehensive urine screening (usually performed off-site) may take several hours or even days. Testing of gastric contents is rarely helpful in the emergency department.

TABLE 295.15
Causes of False-Positive Results in Urine Drug Screens (Immunoassay)

A. Amphetamine
   1. Polyclonal based
      a. Ephedrine
      b. Pseudoephedrine
      c. Chloroquine
      d. Labetalol
   2. Monoclonal based
      a. Chlorpromazine
      b. Flusipirilene
      c. Pipothrazin
      d. Dimethylamylamine
B. Phencyclidine
   1. Doxylamine
   2. Diphenhydramine
   3. Venlafaxine
   4. Dextromethorphan
   5. Tramadol
C. Cannabinoid
   1. Omeprazole
D. Benzodiazepine

   3. Carbamazepine
   4. Thioridazine
   5. Chlorpromazine
   6. Cyclobenzaprine
   7. Quetiapine
F. Methadone
   1. Antipsychotic agents
   2. Diphenhydramine
   3. Doxylamine
   4. Quetiapine
   5. Verapamil
   6. Tapentadol
G. Opiate
   1. Gatifloxacin

Serum quantification of certain toxins is useful, particularly in cases of alcohol (ethanol, methanol, ethylene glycol), acetaminophen, salicylate, phenobarbital, theophylline, digoxin, iron, and lithium intoxication. The timing of these serum specimens needs to correlate with the timing of the drug's absorption and such an analysis is particularly useful in evaluating substances that may exhibit a delay in the onset of clinical symptoms (Table 295.16). Serum values of selected agents causing coma are listed in Table 295.17. A strong argument can be made for checking serum acetaminophen and possibly salicylate levels in all cases of medication ingestion, given the easy availability of acetaminophen and salicylate, the subtle manifestation of early poisoning, and the existence and importance of specific treatment of these potentially lethal intoxications.

TABLE 295.16
Agents that can Cause Delay in Symptoms

Toxic Ingestion	Toxic Dose	Onset of Major Symptomatology (Latent Period)	Time to Determination of Toxic Serum Levels
Acetaminophen	140 mg/kg	72 hrs (hepatic phase)	4 hrs
Salicylates	150 mg/kg	May not take place for 12–24 hrs	6 hrs
Iron	20 mg/kg	12 hrs (shock, seizures)	2–6 hrs
Theophylline			
Regular formulation	10 mg/kg		5 (±3 hrs)
Sustained released	20 mg/kg		11 hrs
Wafarin	0.5 mg/kg	36 hrs (bleeding)	PT depression at 24 hrs
Digoxin	2 mg (child) 5 mg (adult)	3–6 hrs	4 hrs
Phenytoin	Variable	1–2 hrs	3–12 hr
Methanol	4 cc (100% methanol)	6–24 hrs (visual)	1 hrs
Ethylene glycol	1.4 cc/kg	24–72 hrs (renal effects)	1–4 hrs
Bupropion	10 mg/kg	6-18 hrs (seizures)	3 hrs (immediate release)/ 6 hrs (extended release)

TABLE 295.17
Agents and Blood Concentrations Resulting in Coma

Drug	Conventional Units	Drug	Conventional Units
Acebutolol	20 mg/L	Glutethimide	10 mg/L
Acetaminophen	300 µg/mL	Iron	500 µg/dL
Acetone	500 mg/L	Isoniazid	20 mg
Amitriptyline	2 mg/L	Lead	100 µg/dL
Amobarbital	43 mg/L	Lidocaine	5 µg/mL
Baclofen	1 mg/L	Lithium	3 mEq/L
Barbital	160 mg/L	Lorazepam	0.3 mg/L
Butabarbital	39 mg/L	Loxapine	0.7 mg/L
Caffeine	100 mg/L	Meprobamate	60 mg/L
Calcium	15 mg/dL	Mephobarbital	40 mg/L
Carbamazepine	18 mg/L	Methanol	100 mg/dL
Carboxyhemoglobin	30%	Methaqualone	8 mg/L
Carisoprodol	30 mg/L	Methemoglobin	20%
Cetirizine	2 mg/L	Methyprylon	50 mg/L
Chloral hydrate (Trichloroethanol)	20 mg/L	Nomifensine	10 mg/L
Chlordiazepoxide	20 mg/L	Olanzapine	100 µg/L
Chlormethiazole	7 mg/L	Orphenadrine	3 mg/L
Chlormezanone	60 mg/L	Phenobarbital	65 mg/L
Chloroquine	1 mg/L	Phenytoin	40 mg/L
Chlorpromazine	0.5 mg/L	Propoxyphene	1 mg/L
Chlorprothixene	0.8 mg/L	Quetiapine	13 mg/L
Cimetidine	10 mg/L	Quinine	12 µg/mL
Clonazepam	0.07 mg/L	Salicylates	100 mg/dL
Clonidine	2 µg/L	Secobarbital	7 mg/L
Clozapine	2 mg/L	Sodium	160 mEq/dL
Codeine	5 mg/L	Theophylline	40 mg/L
Diazepam	20 mg/L	Tetrahydrocannabinol	180 µg/L
Diethyltoluamide (DEET)	50 mg/L	Toulene	10 mg/L
Digoxin	4 ng/L	Tramadol	2,000 µg/L
Dothiepin	1 mg/L	Tranylcypromine	1 mg/L
Doxepin	0.4 mg/L	Triazolam	31 µg/L
Ethanol	300 mg/dL	Valproic acid	300 mg/L
Ethchlorvynol	50 mg/dL	Venlafaxine	6 mg/L
Gamma hydroxybutyrate	100 mg/L	Zopiclone	300 µg/L
Glucose	800 mg/dL		

Adapted from *Poisoning and Toxicology Handbook*. In: Leikin JB, Paloucek FP, eds. 4th ed. Boca Raton, FL: CRC Press; 2008.

Radiography is not a reliable method for evaluating toxic exposure and should be utilized only in specific cases. Factors that influence radiodensity include molecular weight, atomic number, relative contrast to surrounding tissues, and compactness of the form of drug. Overall, only about one-third of all drug preparations would be detectable by plain abdominal x-ray, with about 2% of drugs being densely radiopaque (Table 295.18) (18). These cases include evaluation of heavy metal exposure (including leaded paint chips), concretion formation of drugs (such as salicylate, meprobamate, iron, and theophylline), suspected body packing or body stuffing, and the use of digital radiography for extended-release formulations (17).

TABLE 295.18
List of Radiopaque Substances

Medicinal	
Amiodarone	Meclizine
Bismuth subgallate	Neostigmine
Bromides	Penicillin G (aqueous)
Calcium carbonate	Potassium chloride
Chloral hydrate	Protriptyline
Chlorpromazine	Ranitidine
Diethylstibestrol	Salicylate
Ethchlorvynol	Sodium chloride
Glyburide	Spironolactone
Haloperidol	Sustained-release medications
Hydroxyzine	Thiamine
Iron	Zinc sulfate
Nonmedicinal/Biologic	
Arsenic	Methylene chloride
Barium	Needlefish
Carbon tetrachloride	Paradichlorobenzene
Chloroform	Tetrachloroethylene
Iopanoic acid	Thallium sulfate
Lead	Trichloroethylene
Mercury	

Common Pitfalls

- Failing to obtain collateral information regarding potential toxin exposure.
- Overlooking potential toxic causes in patients with anion gap metabolic acidosis.
- Overlooking the possibility of acetaminophen toxicity in patients presenting with gastrointestinal or hepatic complaints.
- Failing to consider drug or ethanol withdrawal in the hyperadrenergic delirious patient.

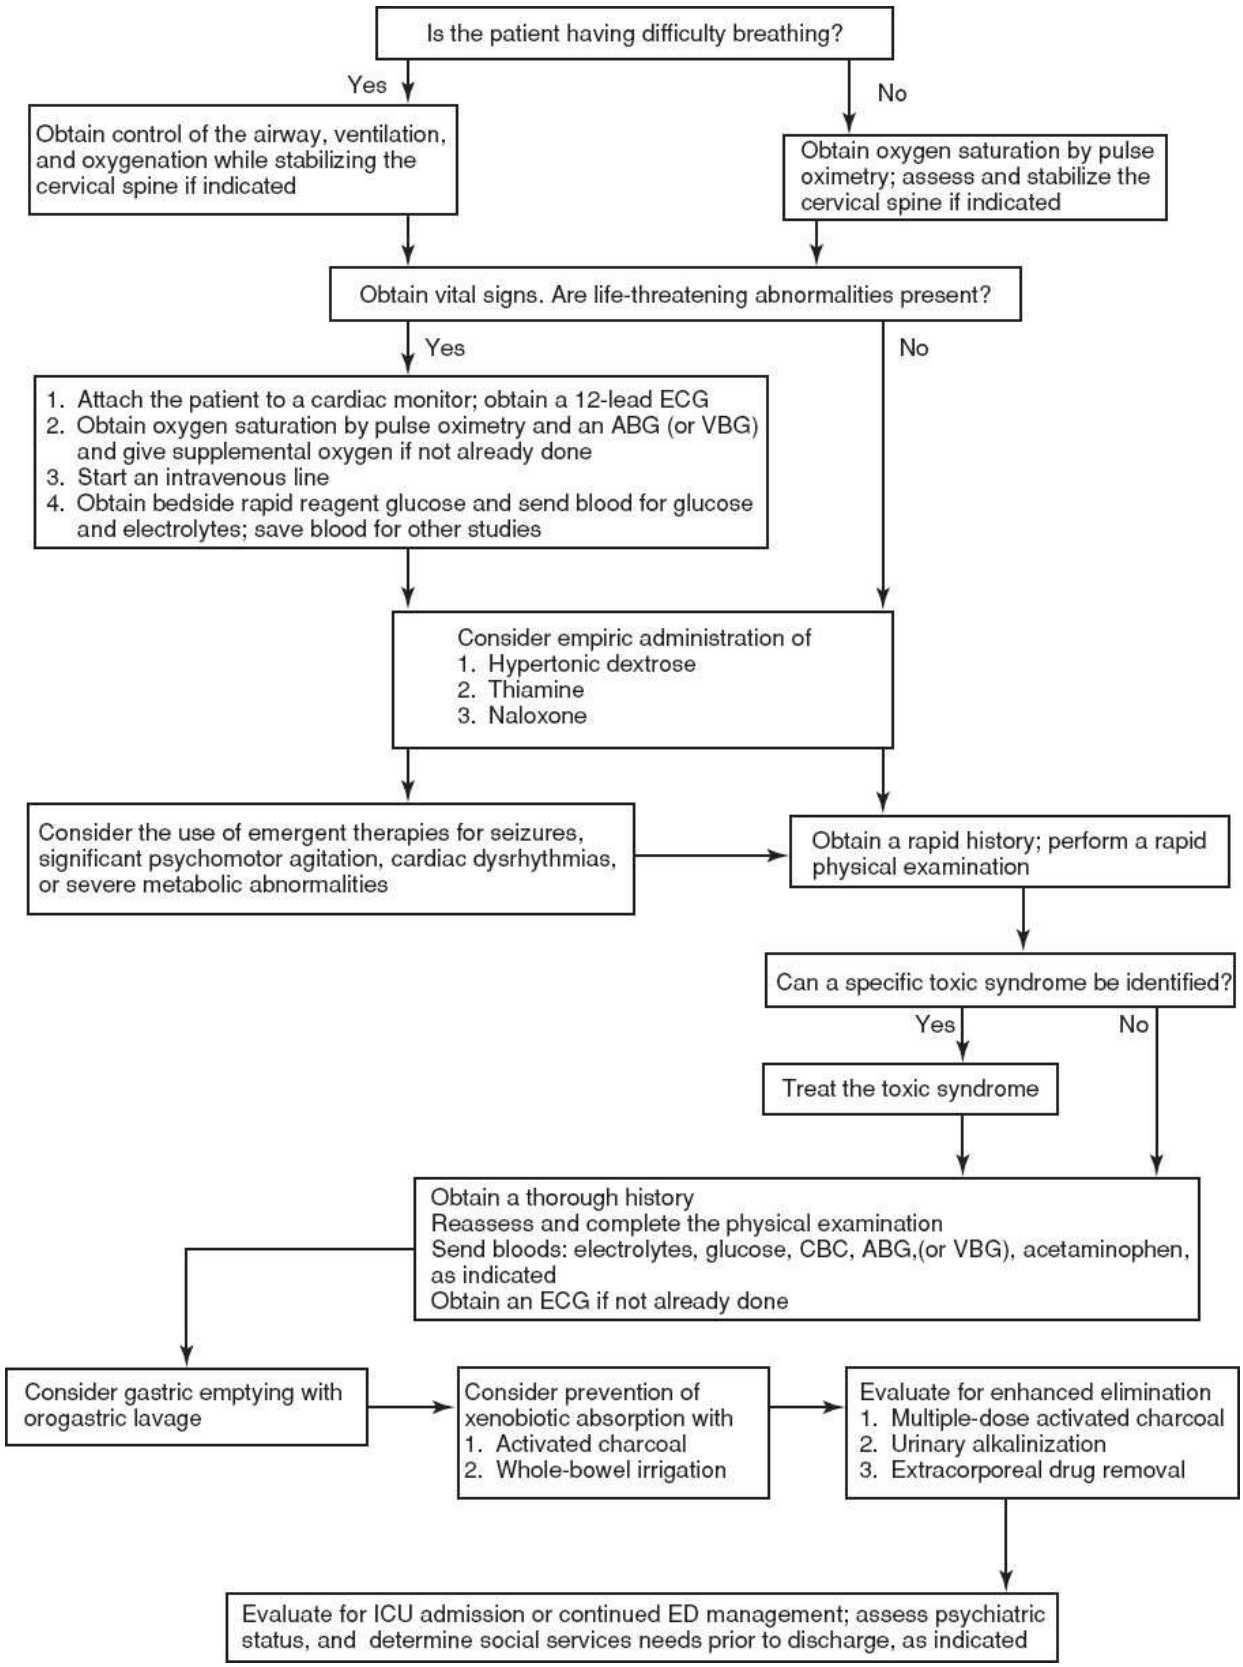
CHAPTER 296

General Management of the Poisoned Patient

Jerrold B. Leikin

The general treatment plan is support of the airway, breathing, and circulation before addressing the poisoning specific treatments with an organized approach essentially similar irrespective of the toxic exposure. This basic poison management encompasses the following intervention (Fig. 296.1):



Is the patient having difficulty breathing?
Yes
No
Obtain control of the airway, ventilation, and oxygenation while stabilizing the cervical spine if indicated
Obtain oxygen saturation by pulse oximetry; assess and stabilize the cervical spine if indicated
Obtain vital signs. Are life-threatening abnormalities present?
Yes
No
1. Attach the patient to a cardiac monitor; obtain a 12-lead ECG
2. Obtain oxygen saturation by pulse oximetry and an ABG (or VBG) and give supplemental oxygen if not already done
3. Start an intravenous line
4. Obtain bedside rapid reagent glucose and send blood for glucose and electrolytes; save blood for other studies
Consider empiric administration of
1. Hypertonic dextrose
2. Thiamine
3. Naloxone
Consider the use of emergent therapies for seizures, significant psychomotor agitation, cardiac dysrhythmias, or severe metabolic abnormalities
Obtain a rapid history; perform a rapid physical examination
Can a specific toxic syndrome be identified?
Yes
No
Treat the toxic syndrome
Obtain a thorough history
Reassess and complete the physical examination
Send bloods: electrolytes, glucose, CBC, ABG,(or VBG), acetaminophen, as indicated
Obtain an ECG if not already done
Consider gastric emptying with orogastric lavage
Consider prevention of xenobiotic absorption with
1. Activated charcoal
2. Whole-bowel irrigation
Evaluate for enhanced elimination
1. Multiple-dose activated charcoal
2. Urinary alkalinization
3. Extracorporeal drug removal
Evaluate for ICU admission or continued ED management; assess psychiatric status, and determine social services needs prior to discharge, as indicated

FIGURE 296.1 The algorithm is a basic guide to the management of poisoned patients. A more detailed description of the steps in management may be found in the accompanying text. This algorithm is only a guide to actual management, which must, of course, consider the patient's clinical status.

1. Prevention of absorption or decontamination
2. Antidote administration, if available
3. Removal of absorbed toxin or enhancing elimination
4. Support and monitoring for adverse effects

PREVENTION OF ABSORPTION

The route of entry for toxic substances can be dermal, ocular, GI, inhalational, or parenteral. Skin decontamination requires removal of the toxin with nonabrasive soap and copious irrigation with water. Contaminated clothing may serve as a reservoir for continued exposure and must be removed with caution and placed in plastic bags or other containers that are impervious to the toxin. This will limit exposure to medical personnel and patient. Ocular decontamination may require prolonged periods of irrigation with normal saline solution using a Morgan lens. Inhalational exposure presents a greater challenge since the toxin cannot be accessed and removed. Most irrigant solutions for ocular, dermal, or gastrointestinal lavage are water or saline based with a few exceptions. The vast majority of toxin exposures and poisonings occur through the gastrointestinal (GI) tract (1). There are three methods of GI decontamination including (1) gastric lavage (GL), (2) whole-bowel irrigation (WBI), and (3) activated charcoal (2,3). Syrup of ipecac, previously used, is relegated to medical history or veterinary toxic exposures (4–7).

Gastric Emptying

GL through a 28- to 40-French Ewald tube is aimed at physically removing an unabsorbed toxin (Table 296.1) (8–10). Before inserting the Ewald tube, the mouth should be inspected for foreign material

and equipment should be ready for suctioning. Large gastric tubes are less likely to enter the trachea than smaller nasogastric tubes, and have large holes to facilitate removal of gastric debris. After insertion, proper position should be confirmed by aspirating stomach contents and auscultating the left upper abdominal quadrant during insufflation of air. Nonintubated patients should be alert (and be expected to remain alert) and have adequate gag reflexes. In unresponsive patients, GL should be performed after a cuffed endotracheal tube has been inserted. Intubation for the sole purpose of gastric emptying is reasonable only if there is a high likelihood that a highly lethal agent remains in the stomach. GL is performed by instilling 200-mL aliquots of warmed tap water until there is clearing of aspirated fluid. After clearing, the Ewald tube may be replaced by a nasogastric tube for subsequent intermittent suctioning and/or administration of activated charcoal.

TABLE 296.1
Toxins which Should be Lavaged with Solutions Other Than Water

Gastric	
Aluminum bif luoride	10% calcium gluconate
Aluminum phosphide or zinc phosphide	Avoid water due to release of phosphine
	Lavage with 1:5,000 potassium permanganate
Barium carbonate	Magnesium sulfate or sodium sulfate
Bromates	Sodium bicarbonate (isotonic or 5% concentration)
Zinc phosphide	
Shellfish exposure	
Tetrodotoxin	
Cesium	Berlin/Prussian blue
Chlorfenvinphos	2% Potassium permanganate or 5% sodium bicarbonate
Rubidium	
Chromium	Ascorbic acid 1% solution (10 g in 1 L)
Creosote	Olive oil
DDT	Mannitol
Fluoride	Calcium gluconate (10%)
Iodine	Starch/sodium thiosulfate (1–5%)
Mercury	Sodium formaldehyde sulfoxylate (20 g in a 5% solution)
	A 2–5% solution of sodium bicarbonate can be used as an alternative therapy
Nicotine	1:5,000 to 1:10,000 potassium permanganate (50–100 mg in 1 L water)
Phosphorus	
Physostigmine	
Quinine	
Strychnine	
Paralytic shellfish (saxitoxin)	2% NaHCO3
Paraquat	1–2 g/kg Fuller's earth (15%) or bentonite (7%)
Radium	Magnesium sulfate (10%)
Sodium monofluoroacetate	
Strontium	Avoid contact with water due to thermal reaction
Thallium	1% sodium iodine
Dermal	
Aluminum phosphide, gallium phosphide, zinc phosphide, elemental lithium, sodium, potassium, Rb, Cs, and Fr	Dry wipe (due to explosive hazard), then rinse with water
Calcium oxide	
Chlorosulfonic acid	
Titanium tetrachloride	
Trichlorosilane	
White phosphorus	
Asphalt	Shur-cleanse or De-solv-it
Chlorobenzylidene malononitrile (CS)	Alkaline solution
Cyanoacrylate	Acetone with soaking in water or nitromethane
Phenol	Polyethlene glycol (300 or 400) or isopropyl alcohol (water is not contraindicated)
Skunk musk	Irrigate with sodium hypochlorite (5.25%) diluted 1:5 or 1:10 or can use a that consisting of 1 quart of 3% hydrogen peroxide, ¼ cup of baking soda, and 1 teaspoon of liquid soap
Chloroacetophenone (mace)	Magnesium hydroxide–aluminum hydroxide–simethicome gently blotted over affected area (avoid eyes)
Ocular	
Aluminum phosphide, gallium phosphide, zinc phosphide, elemental lithium, sodium, potassium, Rb, Cs, and Fr	Dry wipe, then irrigate with water (may react violently with water)
Titanium tetrachloride	
Asphalt	Shur-cleanse or De-solv-it
Calcium hydroxide	2% Sodium edetate
Calcium oxide	
Mercury fulminate	Water followed by 2% sodium thiosulfate solution
Radioactive materials	Normal saline
White phosphorus (if burns develop during water irrigation)	3% Copper sulfate solution (several drops)
Zinc chloride (>1%)	Water followed by (within 2 min of exposure) 1.7% (0.5 molar) edetate disodium solution for 15 min

Activated Charcoal

Charcoal is a by-product of the combustion of compounds such as wood, coconut parts, bone, sucrose, rice, and starch. Its adsorptive

capacity is increased or “activated” by removing materials previously adsorbed with steam heating and chemical treatment, increasing the surface area for adsorption to between 1,000 and 3,000 m^2/g. This results in an inert, nontoxic, and nonspecific adsorbent that binds intraluminal drugs soon after ingestion and thus interferes with their absorption. Single-dose activated charcoal is effective against most toxins and drugs but should be used for cases with a higher probability of injury or illness Table 296.2. It is particularly effective in binding high–molecular-weight compounds and is ineffective for small ions such as lithium or potassium, acids, alkali, hydrocarbons, alcohols, and heavy metals Table 296.3. Activated charcoal decreases serum drug levels in some cases by creating a favorable diffusion gradient between blood and gut, often referred to as *Gastrointestinal dialysis* (8,10,11).

TABLE 296.2
Examples of Substances Removed by Activated Charcoal

Acetaminophen	Fluoxetine
Amphetamines	Isoniazid
Antihistamines	Metformin
Barbituates	Methotrexate
β-Adrenergic blocking agents	Paraquat/Diquat
Calcium channel blocking agents	Quinidine/Quinine
Camphor	Salicylate
Carbamazepine	Strychnine
Cardiac glycosides	Sulfonylurea derivatives
Chlordecone	Theophylline
Chloroquine	Tramadol
Citalopram	Tricyclic antidepressants
Colchicine	Valproic acid
Cyanide salts	Venlafaxine
Escitalopram

TABLE 296.3
Toxins and Drugs Not Absorbed by Activated Charcoal

Alcohols
Hydrocarbons
Organophosphates
Carbamates
Acids
Potassium
Dichloro diphenyl trichloroethane (DDT)
Alkali
Iron
Lithium

Charcoal can be administered after gastric lavage, but it is usually the sole GI decontaminating method (10–12). Airway protection is imperative in stuporous, comatose, or convulsing patients.

Activated charcoal is contraindicated in patients with central nervous system depression with an unprotected airway due to the risk of aspiration. Similarly, hydrocarbon ingestions are also an increased aspiration risk. Individuals at risk for gastrointestinal bleeding or perforation due to previous pathology, recent surgery, or other pre-existing medical conditions may be at increased risk for complications. Activated charcoal should not be administered if endoscopy is being considered. Complications are infrequent; however, charcoal aspiration has been associated with pneumonia, bronchiolitis obliterans, ARDS, and bronchial obstruction, particularly in very young children. Emesis is usually related to use of sorbitol when combined with activated charcoal. Considering the frequency of use of activated charcoal, the complication rate is relatively low but considering the low fatality rate of most poisonings, the greatest benefit is for chemicals or drugs with a high fatality rate such as cyclic antidepressants or calcium channel blockers.

The ideal dose should give a charcoal-to-drug ratio of 10:1. However, since the quantity of poison ingested is usually unknown, the dose is often based on patient weight (0.5 to 1 g/kg). In adolescents and adults, the usual dose is 25 to 100 g. Table 296.2 lists toxins for which charcoal is not particularly effective (13). Based on volunteer studies, the effectiveness of activated charcoal

decreases with time; the greatest benefit is within 3 hours of ingestion although its overall clinical benefit (over that of supportive care) has been challenged (14).

The use of cathartics with activated charcoal may reduce the transit time of drugs and toxins in the GI tract and decrease the constipating effects of charcoal. The two types of osmotic cathartics used are saccharide based (sorbitol) and saline based (magnesium citrate, magnesium sulfate, sodium sulfate. Cathartics may decrease drug absorption but have never been shown to decrease morbidity and mortality or to decrease hospital stay (15–17). Based on available data, the routine use of a cathartic in combination with activated charcoal is not generally recommended (17).

Whole-Bowel Irrigation

WBI with polyethylene glycol electrolyte solution has been used over the past 20 years to prevent toxin absorption by cleansing the gastrointestinal tract. Since no net absorption or secretion of ions occurs, no significant change in water or electrolyte balance would be expected. WBI may have a role in intoxications where activated charcoal is not effective and considered for potentially toxic ingestions of sustained release or enteric-coated tablets, substantial amounts of iron, lead or other metals or ions such as lithium or packets of illicit drugs. The solution is best administered through a small bore 12-French nasogastric tube at age-based dosing: children 9 months to 6 years: 500 mL/hr, children 6 to 12 years: 1,000 mL/hr, adolescents and adults: 1,500 to 2,000 mL/hr. The patient should be seated or the head of the bed elevated to at least 45 degrees to decrease the likelihood of emesis and establish a dependent relationship of the intestines to the stomach. If emesis occurs, the infusion rate can be decreased by 50% for 30 to 60 minutes and then return to the original rate. Metoclopramide (which exhibits both antiemetic and gastric emptying effects) can also be administered.

The solution is administered until the rectal effluent is clear which may take over 5 hours. The technique is time consuming and requires a cooperative patient. Most studies supporting this approach

are limited to case reports, and there are no established specific indications for its use (2,18,19). Contraindications to WBI include ileus, GI hemorrhage, uncontrolled vomiting, bowel perforation, and an unprotected compromised airway.

Antidotes

An antidote is a substance that increases the mean lethal dose of a toxin, or that can favorably affect the toxic effects of a poison. Some are toxic themselves and should be used only when indicated. Only approximately 5% of overdose patients require antidotal administration (1).

Table 296.4 lists antidotes for specific drugs/poisons. These will be discussed in the individual toxin chapters.

TABLE 296.4
Examples of Antidotes

Poison/Drug/Toxin	Antidote
Acetaminophen	N-Acetylcysteine
Carbon tetrachloride	
Other hepatotoxins	
Acetonitrile	Hydroxocobalamin
Acrylonitrile	
Cyanide (e.g., HCN, KCN and NaCN)	
Cyanogenic glycoside natural sources (apricot pits and peach pits)	
Laetrile	
Smoke inhalation (combustion of synthetic cyanogenic materials)	
Pit viper envenomation (e.g., rattlesnakes, cottonmouths, and copperheads)	
Black widow spider envenomation	Antivenom: *Latrodectus mactans* (black widow spider)
Lead	Calcium disodium EDTA
Zinc salts (e.g., zinc chloride)	
Propanolol	Calcium chloride and Calcium gluconate
BlackwWidow spider (*Latrodectus mactans) envenomation*	
Calcium channel blockers	
Fluoride salts (e.g., NaF)	
Hydrofluoric acid (HF)	
Hyperkalemia (not digoxin-induced)	
Hypermagnesemia	
Centruroides scorpion envenomation (grade IV)	Centruroides scorpion antisera
Eastern coral snake	Antivenin—micruros fulvius
Texas coral snake	
Iron	Deferoxamine mesylate
Aluminum accumulation renal failure	
Cardian glycoside–containing plants (e.g., foxglove and oleander)	Digoxin immune fab
Digitoxin	
Digoxin	
Arsenic	Dimercaprol
Copper	
Gold	
Lead	
Mercury	
Benzodiazepines	Flumazenil
Zolpidem	
Methanol	Folic acid
Methotrexate, trimetrexate	Folinic acid (leucovorin)
Pyrimethamine	
Trimethoprim	
2-Butoxyethanol	Fomepizole
2-Chloroethanol	
Diethylene glycol	
Ethylene glycol	
Methanol	
Propylene glycol	
β-Blockers	Glucagon
Calcium channel blockers	
Hypoglycemia	
Hypoglycemic agents	
Carbon monoxide	Hyperbaric oxygen (HBO)
Carbon tetrachloride	
Cyanide	
Hydrogen sulfide	
Brown recluse spider (*Loxosceles recluse or lampona cylindrata) envenomation*	
Ergotamine-induced peripheral ischemia	
Methemoglobin-inducing agents	Methylene blue
Opioids	Naloxone
Tramadol	
Arsenic	D-Pencillamine
Copper	
Gold	
Mercury	
Anticholinergic alkaloid–containing plants and drugs	Physostigmine salicylate
Indanedione derivatives	Phytonadione
Long-acting anticoagulant rodenticide	
Warfarin	
Antimyasthenic agents (e.g., pyridostigmine)	Pralidoxime chloride (2-PAM) and atropine
Nerve agents (e.g., sarin, soman, tabun and VX)	
Organophosphate insecticides	
Tacrine	
Enoxaparin	Protamine sulfate
Heparin	
Acrylamide	Pyridoxine hydrochloride (vitamin B_6)
Cycloserine	
Ethylene glycol	
Hydrazine	
Isoniazid (INH)	
Monomethylhydrazine-containing mushrooms (e.g., Gyromitra)	
Chlorine gas	Sodium bicarbonate
Serum alkalinization for phenobarbitol salicylate	
Agents producing a quinidine like effect as demonstrated by widened QRS complex on EKG	
Arsenic	Succimer
Lead	
Mercury

ENHANCEMENT OF ELIMINATION

Forced Diuresis and Urinary pH Manipulation

Routine use of volume loading to promote diuresis has not been supported in the literature and is not recommended. Manipulation of urinary pH can be used therapeutically to enhance elimination of some intoxicants (Table 296.5). The limits of urinary pH are 4.5 to

7.5 under conditions of enhanced acidification and alkalinization. Thus, elimination of very strong (negative logarithm of the acid ionization equilibrium constant [p*K*a] <3) or very weak (p*K*a >8) acids is unaltered by urinary pH manipulation. Other acidic or basic drugs do not undergo renal tubular absorption, irrespective of urinary pH, since they are polar in their nonionized form. Urinary alkalinization (pH >7.5) is most often used to eliminate salicylates and phenobarbital (20). It can be achieved by administration of IV sodium bicarbonate (1 to 2 mEq/kg every 3 to 4 hours); this may be administered as two 50-mL ampules of 8.4% sodium bicarbonate (each containing 50 mEq of $NaHCO_3$) per liter of 5% dextrose in water infused at 250 mL/hr. Complications of this therapy include alkalemia (particularly in the presence of concurrent respiratory alkalosis), volume overload, hypernatremia, and hypokalemia. It is particularly important to avoid hypokalemia, which prevents excretion of alkaline urine by promoting distal tubular potassium reabsorption in exchange for hydrogen ion. Accordingly, bicarbonate administration in the presence of significant hypokalemia will not alkalinize the urine, yet will increase the risk of alkalemia. Since urinary alkalinization therapy can cause hypokalemia (due to alkalemia-induced intracellular potassium shift and increased urinary potassium loss with alkaline diuresis), addition of potassium chloride to the bicarbonate infusion is frequently required. Acetazolamide should not be used to alkalinize urine. Resultant metabolic acidosis can increase toxicity of certain poisonings (particularly with salicylate poisoning).

TABLE 296.5
Toxins Eliminated by Urinary Alkalinization

2,4 Dichlorophenoxy acetic acid
Chlorpropramide

Multiple-Dose Activated Charcoal

Multiple-dose activated charcoal (MDAC) can be an effective way to enhance the elimination of toxins that have been absorbed (21). The mechanism by which this modality accomplishes enhancement of elimination is either by interrupting the enterohepatic/enterogastric circulation of drugs or through the binding of any drug that diffuses from the circulation into the gut lumen (called *GI dialysis*). However, it has limited application because the toxin must have a low volume of distribution, low protein binding, prolonged elimination half-life, and low p*K*a, which maximizes transport across mucosal membranes into the GI tract. Although optimal dosage and frequency of administration following the initial dose of activated charcoal is not well established, most experts recommend a dose of approximately 0.5 g/kg every 2 to 4 hours for at least three doses. Cathartics are generally not administered to avoid hypernatremia, hypokalemia, and hypermagnesemia. MDAC should be used with caution in patients with decreased bowel sounds, abdominal distension, and persistent emesis. Unless a patient has an intact or protected airway, the administration of multidose charcoal is contraindicated. A review of the literature reported that although MDAC enhances drug elimination significantly, it has not yet been evaluated in a controlled trial of poisoned patients with the objective of demonstrating a reduction in morbidity and mortality. Table 296.6

provides a list of drugs and toxins where there may be a role for MDAC. However, based on experimental and clinical studies, it should be considered in patients with a life-threatening ingestion of carbamazepine, dapsone, phenobarbital, quinine, or theophylline.

TABLE 296.6
Toxins and Drugs Eliminated by Multiple Dosing of Activated Charcoal[a]

Amitriptyline	Meprobamate
Amoxapine	Methyprylon
Baclofen (?)	Nadolol
Benzodiazepines (?)	Nortriptyline
Bupropion (?)	Phencyclidine
Carbamazepine	Phenobarbital
Chlordecone	Phenylbutazone
Dapsone	Phenytoin (?)
Diazepam	Piroxicam
Digitoxin	Propoxyphene
Digoxin	Quinine
Disopyramide	Salicylates (?)
Glutethimide	Sotalol
Maprotiline	Theophylline

Extracorporeal Removal of Toxins

Although clear proof that extracorporeal toxin removal favorably alters the course of any intoxication is generally lacking, it should be considered when the intoxication is projected to undergo delayed or insufficient clearance because of either organ dysfunction, the intoxicating agent produces toxic metabolites, or delayed toxicity is characteristic of the intoxication. Three methods for extracorporeal removal of toxins are possible: (1) dialysis (usually hemodialysis rather than peritoneal dialysis), (2) hemoperfusion, and (3) hemofiltration (22,23). Plasmapheresis is rarely used although effective in reducing plasma levels of several drugs with high plasma protein binding (>80%) and a low volume of distribution (<0.2

L/kg) (Table 296.7) (24,25). Exchange transfusion has been used for neonatal/infant exposures (Table 296.8); therapeutic plasma exchange (TPE) with fresh frozen plasma has been used to remove toxins that are protein bound and not removed by dialysis (i.e., organophosphate insecticides, mushrooms) (26,27).

TABLE 296.7
Toxicants in which Plasmapheresis Has been Shown to Enhance Elimination

Amanita phalloides (mushrooms)
Amphotericin B
Amytriptylline
Caffeine
Carbamazepine
Diltiazem
L-Thyroxine
Maprotyline
Mercury
Paraquat (decreased level by 80%)
Pentachlorophenol
Phenytoin
Propranolol
Theophylline
Tobramycin
Vanadate
Verapamil

Hemodialysis

Hemodialysis is the primary extracorporeal method to remove toxins or drugs. Ideal toxins for hemodialysis have a low molecular weight (<500 d), water soluble, low protein binding (<70% to 80%), and a small volume of distribution (<1 L/kg). It is also effective in correcting concomitant electrolyte abnormality and metabolic acidosis. Toxins in which hemodialysis may be required in an early stage of intoxication include methanol, ethylene glycol, boric acid, salicylates, and lithium. Others are listed in Table 296.9. Hemodialysis can also be used for heavy metal chelation in patients with renal failure.

TABLE 296.9
Some Toxins and Drugs Removed by Hemodialysis

Bromide
Ethylene glycol
Isopropanol
Metformin
Methanol
Lithium
Phenobarbital
Salicylate
Valproic acid

Adapted from *Poisoning and Toxicology Handbook*. 4th ed. CRC Press; 2008:1231–1232.

Hemoperfusion

Hemoperfusion is essentially the parenteral analog of oral activated charcoal. Most drugs are extractable by hemoperfusion, which is particularly suitable for extracorporeal removal of toxins that are of high molecular weight, highly protein bound, or lipid soluble. It has been effectively used to enhance elimination of theophylline, phenobarbital, phenytoin, carbamazepine, paraquat, and glutethimide. Due to the lack of availability of charcoal cartridges, this modality is rarely available.

Hemofiltration

Hemofiltration achieves drug and toxin removal by convection. It transports solutes through a highly porous membrane that is permeable to substances with weights of up to 6,000 d, including virtually all drugs. In some cases, hemofiltration membranes are permeable to substances weighing up to 20,000 d. Although the application of this technique has not been vigorously studied in poisoned patients, there are increasing numbers of case reports of extracorporeal intoxicant removal by continuous arteriovenous or venovenous hemofiltration methods. Hemofiltration is potentially useful for removal of substances with a large volume of distribution, slow intercompartmental transfer, or extensive tissue binding. Specific highly porous hemofiltration cartridges are useful for removal of large–molecular-weight solutes or complexes, such as

combined digoxin–Fab fragment complexes, or desferoxamine complexes with iron or with aluminum.

Lipid Rescue Resuscitation

Lipid emulsion infusion was first demonstrated in 1998 to improve resuscitation due to cardiovascular collapse from bupivacaine overdose (28). Since then, successful treatment of cardiovascular toxicity from a wide range of lipophilic drugs (such as calcium channel blocking agents, β-adrenergic blockers, tricyclic/SSRI antidepressants, and other local anesthetics) has been achieved by lipid or intralipid rescue. The therapeutic mechanisms of lipid emulsion infusion has been postulated to be (28): (1) lipid emulsion capture of drug ("lipid sink"), (2) mitochondrial uptake of fatty acid (metabolic effect), (3) Interference of cellular membrane sodium channel, (4) cytoprotection by inhibition of glycogen synthase kinase, and (5) calcium entry promotion through voltage-dependent calcium channels resulting in a cardiac inotropic effect.

The suggested dosage of a 20% lipid emulsion is a 1.5 mL/kg bolus over 2 to 3 minutes followed by an infusion of 20% lipid emulsion at a rate of 0.25 mL/kg/min (29,30). For asystolic patients, or those who do not respond to the bolus, the dose may be increased if hemodynamic instability remains. Whenever possible, lipid emulsion therapy should be terminated within 1 hour. Hyperamylasemia and hypertrilyceridemia have been reported following lipid emulsion therapy; however, this therapy has otherwise been shown to be relatively free of complications (27,30). Thus, the therapeutic profile of this intervention is quite promising and its use will likely increase to emergently reverse the cardiovascular effects of drug toxicity (30).

DISPOSITION

Indications for ICU Admission

In the current healthcare climate, the practice of routinely admitting the poisoned patient to the ICU is being questioned. Brett et al. (31) identified eight clinical risk factors that can predict ICU interventions: (1) $PaCO_2$ >45 mm Hg, (2) need for endotracheal

intubation, (3) toxin-induced seizures, (4) cardiac arrhythmias, (5) QRS duration ≤0.12 seconds, (6) systolic BP <80 mm Hg, (7) second- or third-degree atrioventricular block, and (8) unresponsiveness to verbal stimuli . In this retrospective study, if a poisoned patient did not exhibit any of the eight characteristics, no ICU interventions (intubation, vasopressors or antiarrhythmics, and dialysis or hemoperfusion) were required (31). Other indications for ICU admission include a Glasgow Coma Scale score <12, need for emergency dialysis or hemoperfusion, progressive metabolic acidosis, and a cyclic antidepressant or phenothiazine overdose with signs of anticholinergic cardiac toxicity (32). An important critical care intervention is extracorporeal membrane oxygenation (ECMO). Even though it has been used since 1972, recent advances in ECMO technology have rendered it more biocompatible. Thus it is increasingly being used as a salvage therapy for acute respiratory distress syndrome and circulatory shock, for up to 3 days, in certain exposures such as calcium channel antagonists, β-adrenergic blockers, tricyclic antidepressants, chloroquine, colchicine and hydrocarbons/inhalation toxic exposure (33). Severe hyperkalemia, wide alterations in body temperature, and the need for continuous infusion of naloxone are also reasons to admit a patient to an ICU. Hypotension on admission is the most significant predictor of fatality (34,35). In addition, staffing issues such as the availability of a "sitter" in cases of attempted suicide may impact patient disposition. Table 296.10 provides a list of criteria for ICU admission.

TABLE 296.10
Criteria for Admission of the Poisoned Patient to the ICU

Respiratory depression ($Paco_2$ >45 mm Hg)
Emergency intubation
Seizures
Cardiac arrhythmia (second- or third-degree atrioventricular block)
Systolic Blood Pressure <80 mm Hg in adults
Unresponsiveness to verbal stimuli
Glasgow Coma Scale score <12
Need for emergency dialysis, hemoperfusion, or ECMO
Increasing metabolic acidosis
Pulmonary edema induced by toxins (including inhalation) or drugs
Hypothermia or hyperthermia including neuroleptic malignant syndrome
Tricyclic or phenothiazine overdose manifesting anticholinergic signs, neurologic abnormalities, QRS duration >0.12 s, or QT >0.5 s
Body packers and stuffers
Concretions caused by drugs
Emergency surgical intervention
Administration of pralidoxime in organophosphate toxicity
Antivenom administration in Crotalidae, coral snake, scorpion, or arthropod envenomation
Need for continuous infusion of naloxone
Hypokalemia secondary to digitalis overdose (or need for digoxin-immune antibody Fab fragments)
Administration of Lipid Rescue Therapy
Cerebral edema
Monoamine oxidase inhibitor toxicity
Significant aspiration pneumonitis in the elderly
Delirum tremens

ECMO, extracorporeal membrane oxygenation.

In addition, the physician should be aware of certain ingestions, that in a single-dose form, can be potentially catastrophic to a toddler (Table 296.11) (36,37).

TABLE 296.11
Toxins/Medications that Could Cause Fatality in a Toddler (Under 20 kg Weight) if Ingested in a Single Dose Form

A. Tablets/Capsules
Amantadine
Amoxapine
Amphetamines
Benzonatate
β-Adrenergic blockers
Buspirone
Calcium channel blockers
Chloroquine (>20 mg/kg)
Chlorpramazine (>25 mg/kg)
Clonidine
Clozapine
Codeine (>1 mg/kg)
Colchicine
Cyclobenzaprine
Diflunisal
Diltiazem
Disopyramide (>15 mg/kg)
Ecstacy (3,4-methylenedioxy-methamphetamine)
Flecainide (>25 mg/kg)
Haloperidol
Hydrocodone (>2.5 mg)
Hydroxychloroquine (>20 mg/kg)
Hypoglycemic agents (sulfonylureas)
Imipramine
Isradipine (>2.5 mg)
Lithium
Lomotil
Loxapine (>30 mg/kg)
Mefanamic acid
Meprobamate
Methadone (>1 mg/kg)
Mollindone
Monoamine oxidase inhibitors
Nifedipine (>15 mg/kg)
Olanzapine (>10 mg/kg)
Phenothiazines
Prazosin
Procainamide
Quinidine
Quinine (>80 mg/kg)
Terazosin
Theophylline (>8 mg/kg)
Thioridazine (15 mg/kg)
Trazadone
Verapamil

B. Ointments/Cream
Camphor (>100 mg/kg)
Doxepin
Methyl salicylate (oil of wintergreen)
Theophylline

C. Patches
Clonidine
Fentanyl
Nicotine
Nitroglycerin

D. Opthalmic
Atropine
Imidazoline
Scopalomine
Acetonitrile
Ammonia (>10% concentration)
Ammonium fluoride
Arsenic (inorganic)
Benzocaine
Boric acid
Butyrolactone
Diethylene glycol
Ethylene glycol (>1 mL/kg)
Formaldehyde
Hydrofluoric acid
Mercury (inorganic)
Methyl alcohol
Methylene chloride
Nicotine sulfate
Nitroethane
Pennyroyal oil
Selenious acid
Strychnine
Thallium
Toluene
Zinc chloride

E. Miscellaneous
Boric acid
Bromates (over 2% concentration)

Common Pitfalls

- Failure to consider decontamination procedures upon presentation.
- Failure to consider delayed onset of the effects of certain toxins.
- Failure to institute extracorporeal removal techniques in a timely manner.
- Failure to consider seriously certain medications, which in a single-dose form, can be lethal to a toddler.

PART 2 • ALCOHOL-RELATED AGENTS

CHAPTER 297

Ethanol

Michael A. Darracq and Binh T. Ly

Ethanol, or ethyl alcohol, is a two-carbon chain alcohol with the chemical formula CH_3CH_2OH. Ethanol is often commonly referred to as simply "alcohol." However, other alcohols such as ethylene glycol (Chapter 299), methanol (Chapter 300), and isopropyl alcohol (isopropanol) (Chapter 301) also have significant and individual toxicities. Ethanol is unique among potential drugs of abuse in that it is legally and culturally accepted in most societies of the world and is therefore ubiquitous.

A standard "drink" contains about 14.4 g of ethanol. This is the amount of ethanol found in 1.5 oz of 80-proof liquor (40% alcohol by volume), 5 oz of wine (12% alcohol), or 12 oz of beer (5% alcohol). Ethanol is also found in many other commercially available products, including mouthwash, aftershave, cooking ingredients (e.g., vanilla extract), pharmaceutical agents (e.g., elixirs and tinctures), and gel- or foam based hand-sanitizers.

The American Psychiatric Association (APA) *Diagnostic and Statistical Manual of Mental Disorders, 5th edition* defines alcohol use disorders according to the following 11 criteria: (1) Taking the substance (ethanol) in larger amounts or for longer than was intended; (2) wanting to cut down or stop but not managing to; (3) spending a lot of time getting, using, or recovering from use; (4) cravings and urges to use the substance; (5) not managing to do what one should at work, home or school, because of use; (6) continuing to use, even when it causes problems in relationships; (7) giving up important social, occupational or recreational activities

because of use; (8) using ethanol again and again, even when it puts the user in danger; (9) continuing to use, even when the user knows they have a physical or psychological problem that could have been caused or made worse by use; (10) needing more of the substance to get the effect wanted (tolerance); (11) development of withdrawal symptoms, which can be relieved by taking more of the substance (1). The DSM V allows classification of the severity of the disorder on the basis of how many symptoms are identified. Two or three symptoms indicate mild use disorder, four to five symptoms indicate moderate, and six or more symptoms indicate a severe disorder.

Ethanol is rapidly absorbed from the gastrointestinal (GI) tract with up to 90% of an ingested dose absorbed within 1 hour. Twenty percent of ingested ethanol is absorbed in the stomach, with the remainder absorbed by the small intestine (2). Enhanced absorption occurs in the presence of rapid gastric emptying, absence of other gastric contents, carbonation and ethanol concentration in solution with a 20% ethanol solution most readily absorbed. Delays in absorption may occur with higher concentrations of ethanol due to pylorospasm, presence of food in stomach, congestion of other drugs and other individual variability (2).

Ethanol is principally eliminated by the liver. Only a small portion of absorbed ethanol is excreted unchanged in the urine. Alcohol dehydrogenase (ADH) is the primary enzyme for alcohol metabolism (3) which begins prior to systemic absorption. When ethanol contacts the gastric mucosa, a subtype of ADH located in the stomach begins oxidation of ethanol to acetaldehyde. Once absorbed, ethanol is oxidized to acetaldehyde by an additional class of ADH located in the liver. Acetaldehyde is subsequently metabolized by aldehyde dehydrogenase (ALDH) to acetate. Acetate is eliminated as carbon dioxide and water. Genetic polymorphisms in ADH and ALDH determine the extent to which acetaldehyde accumulates after alcohol consumption and affect individual susceptibilities to the toxic effects of ethanol and tendencies toward alcohol dependence and abuse (3). ADH is saturated at relatively low blood-ethanol concentrations ($<$10 mg/dL) (4). Saturation results in elimination converting from first-order to zero-order

kinetics and a longer half-life. The 70-kg adult male metabolizes 7 to 10 g of alcohol per hour, corresponding to an hourly decrease of the blood-ethanol level of approximately 15 to 20 mg/dL/hr (5).

The enzyme catalase and cytochrome P450 enzymes also oxidize ethanol to acetaldehyde. Under normal physiologic conditions, catalase contributes only a minor role to ethanol metabolism. Cytochrome P450 (CYP) 2E1 accounts for the majority of non-ADH metabolism of ethanol in the liver. CYP1A2 and 3A4 also contribute to ethanol metabolism to a lesser extent. While ADH is responsible for the majority of ethanol metabolism, CYP2E1 is inducible and its enzymatic activity increases in the presence of higher ethanol concentrations and after extended ethanol intake (3).

In the oxidation of ethanol to acetaldehyde (ADH) and acetaldehyde to acetate (ALDH), nicotinamide adenine dinucleotide (NAD^+) is used as a hydrogen acceptor. The accumulation of NADH impairs the cell's ability to perform oxidative reactions and can lead to numerous metabolic abnormalities, including impairments of gluconeogenesis (Fig. 297.1). Although this has minimal consequence in normal adults, it may lead to significant hypoglycemia in children and malnourished alcoholics who have limited glycogen stores, particularly. The conversion of NADH back to NAD^+ requires oxygen. When large amounts of ethanol are metabolized, oxygen requirements in the centrilobular areas of the liver exceed its delivery, resulting in a relative hypoxia in these areas, which is believed to contribute to hepatic damage.

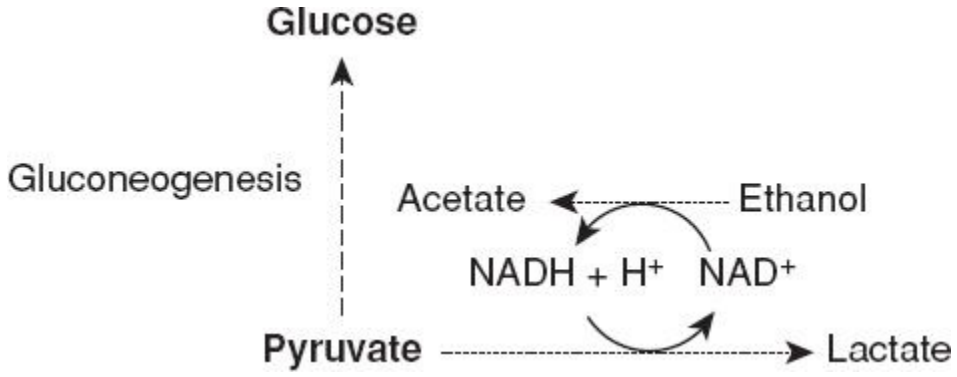

FIGURE 297.1 Mechanism of ethanol-induced hypoglycemia. During the course of ethanol metabolism, the formation of NADH

favors the conversion of pyruvate to lactate rather than to glucose.

Increased oxygen demand also shifts the oxidation–reduction potential of the cell. The result of this shift is an increased ratio of lactate to pyruvate, which favors glycolysis and depletes available glycogen stores. The increase in free hydrogen ions (H^+) tends to favor ketone formation and fatty acid generation. Excess H^+ depresses the citric acid cycle and decreases the use of free fatty acids as an energy source. Ethanol-induced metabolic derangements, especially with poor nutritional status, increase the risk of developing ketoacidosis and hypoglycemia. Renal magnesium wasting, secondary to ethanol's inhibitory effect on magnesium resorption, combined with intestinal malabsorption of magnesium, contribute to development of hypomagnesemia in chronic alcoholics. Pyruvate, which is normally converted to acetyl coenzyme A using thiamine as a cofactor, is converted instead to lactate (Fig. 297.1). Thiamine is a water-soluble nutrient with a limited 10-day supply in the body. Thiamine deficiency, usually because of poor nutrition, may lead to life-threatening lactic acidosis.

The exact mechanisms of ethanol inebriation are still unclear, but current theories suggest that ethanol acts upon a variety of neurotransmitters. Specific receptors for ethanol have not been identified but ethanol enhances the inhibitory effects of γ-amino butyric acid (GABA) at subtype A ($GABA_A$) receptors while blocking the N-methyl-D-aspartate (NMDA) subtypes of excitatory glutamate receptors (6). Ethanol may appear to be stimulating when it selectively depresses inhibitory mechanisms in the brain.

If ethanol is coingested with other sedative-hypnotic agents, it increases the sedative effects of these agents and increase CNS and respiratory depression. These include benzodiazepines, phenothiazines, barbiturates, γ-hydroxybutyrate (GHB), chloral hydrate, cyclic antidepressants, antihistamines, and opioids, among others.

Ethanol is one of the most common substances involved in drug-facilitated sexual assault (DFSA). This most commonly occurs as a result of voluntary ethanol consumption by the victim. Additional substances may or may not be added to the victim's drink leading to further psychomotor depression and amnesia (see Chapter 309).

CLINICAL PRESENTATION

Clinical manifestations following acute ethanol consumption are variable and caution must be employed when trying to attribute ethanol-related signs or symptoms to any specific serum ethanol concentration. The effects of ethanol are dependent on the degree to which the drinker has been habituated. Without knowing the pattern of individual ethanol use, it is difficult to associate a particular ethanol concentration with specific clinical symptoms.

At lower dosages, ethanol's depression of inhibitory pathways in the brain may lead to CNS stimulation through disinhibition. These effects are most pronounced in mildly to moderately intoxicated individuals who engage in functions requiring higher degrees of cortical integration. Individuals may exhibit euphoria, gregariousness, verbosity, or emotional lability. Frequently, disinhibited behavior reflects the individual's basic personality and results in more boisterous or aggressive behavior. Other clinical manifestations may include ataxia, nystagmus, and impairments in reaction time. With deeper levels of intoxication, disinhibition and impairment of cognitive integration may be progressive. Overt displays of hostility and aggressiveness emerge. With severe ethanol intoxication, profound CNS depression, coma, and respiratory depression occur with an increased risk of morbidity as concomitant loss of airway-protective reflexes may ensue.

An acutely ethanol-intoxicated patient may present with classic features that include flushed skin, diaphoresis, tachycardia, hypothermia, hypoventilation, vomiting, dysarthria, and incoordination. Diplopia, visual disturbances, and nystagmus may be evident which may occur from the direct toxic effects of ethanol or may represent Wernicke encephalopathy. Acute heavy ethanol

consumption may be associated with myocardial ischemia in patients with underlying but otherwise stable cardiac disease (4).

The association between ethanol use and cardiac dysrhythmias in otherwise healthy individuals has been referred to as “holiday heart syndrome.” This syndrome was first described in individuals with heavy but sporadic ethanol ingestion such as on holidays and weekends. The most common dysrhythmia is atrial fibrillation, which typically resolves within 24 hours. Although dysrhythmias may occur, they are usually benign and rate control may be the only acute intervention necessary. Long-term antidysrhythmics are not generally necessary.

Hypoglycemia may develop because gluconeogenesis is impaired by rising levels of NADH produced during ethanol metabolism, particularly in the malnourished adult or the young child. Ethanol-induced hypoglycemia may lead to altered sensorium and seizures.

Clinical findings and systemic effects suggestive of chronic alcohol abuse are listed in Table 297.1. Memory difficulties and other cognitive impairments may occur in alcoholics who are otherwise able to function socially or occupationally. GI dysfunction (including abdominal pain, diarrhea, vomiting, hematemesis) because of direct gastric irritation by ethanol or secondary processes such as pancreatitis or hepatitis may occur. Respiratory complaints, frequent infections, weakness, polysubstance use, withdrawal, or recurrent trauma may also occur.

TABLE 297.1
Clinical Manifestations of Alcohol Abuse

Nervous System
Inebriation
Seizures
Dementia
Coma
Wernicke–Korsakoff psychosis
Polyneuropathy
Amnesia
Hallucinosis
Withdrawal

Cardiovascular System
Autonomic dysfunction
Congestive cardiomyopathy
Holiday heart (dysrhythmias)
"Wet" Beriberi (thiamine deficiency)

Gastrointestinal System
Alcoholic hepatitis
Steatosis
Alcoholic cirrhosis
Esophagitis
Gastritis
Peptic-ulcer disease
Gastrointestinal bleeding
Chronic diarrhea
Pancreatitis (acute or chronic)
Pancreatic pseudocyst
Varices and hemorrhoids
Ascites
Malabsorption and malnutrition
Cancers of the gastrointestinal tract (mouth, pharynx, esophagus, larynx)
Boerhaave syndrome
Mallory Weiss tear

Genitourinary System
Uric-acid nephropathy
Acute tubular necrosis
Hepatorenal syndrome
Hypogonadism
Impotence
Infertility

Hematologic
Myelosuppression
Coagulopathies
Microcytic anemia
Megaloblastic anemia
Thrombocytopenia
Leukopenia

Infectious
Pneumonia
Spontaneous bacterial peritonitis

Metabolic
Ketoacidosis
Electrolyte abnormalities
Vitamin deficiencies
Hypothermia
Hypoglycemia
Malnutrition
Hypertriglyceridemia

Musculoskeletal
Myopathies
Gout
Rhabdomyolysis

Pulmonary
Sleep apnea
Chronic respiratory insufficiency
Tuberculosis

Psychiatric
Anxiety
Insomnia
Irrational behaviors
Borderline personality
Polysubstance abuse

Adolescents may present to the ED with a myriad of nonspecific complaints, none of which may directly point to alcohol abuse as a possible underlying etiology. Obtaining a history from family members can be invaluable. The adolescent may have recently undergone significant changes in personality, behavior, peer contacts, or peer relations. College-aged alcoholics, who may use the ED as their only source of healthcare, can present with vague flu-like symptoms, headache, insomnia, chest palpitations, trauma, GI disturbances, or psychiatric complaints. Young, otherwise healthy males presenting with chest palpitations, showing paroxysmal atrial fibrillation, atrial tachycardia, or frequent atrial extrasystoles, should be questioned about their ethanol use. Geriatric alcoholics may be brought to the department by their families with altered mental status, daytime sleepiness, and irrational behavior.

Occasionally, chronic alcoholics are treated with disulfiram (Antabuse) to encourage abstinence. Disulfram blocks ALDH and allow accumulation of acetaldehyde so that small amounts of ethanol may induce an adverse reaction. Signs and symptoms of the disulfiram-ethanol reaction (DER) include flushing of the face and body, tachycardia, sensations of warmth, urticaria, pruritus, light-headedness, headache, nausea, and vomiting. Complaints of palpitations, chest pain, and shortness of breath are common. In addition, disulfiram may cause inhibition of dopamine-β-hydroxylase, blocking the conversion of dopamine to norepinephrine, which may lead to hypotension and hypoperfusion. Myocardial ischemia is usually only associated with severe hypotension. In general, deaths attributable to DERs are extremely rare. Manifestations of DER usually begin within 30 minutes of ethanol exposure and may last for several hours. A number of other compounds may induce a disulfiram-like reaction in the presence of ethanol (Table 297.2). The source of ethanol exposure may be elusive because ethanol-containing products in the home are ubiquitous. A high percentage of Asians have a genetic lack of ALDH and have an identical reaction to taking disulfram with ethanol exposure. Similar findings may result from exposure unrelated to

ethanol, such as niacin, monosodium glutamate, rifampin, vancomycin, boric acid, and scombroid poisoning.

TABLE 297.2
Causes of Disulfiram-Like Reactions Following Ethanol Exposure

Mushrooms	*Coprinus* sp. mushrooms
Chemicals	Carbon disulfide
	Carbon tetrachloride
	Tetramethylthiuram (thiram)
	Trichloroethylene
Medications	Antimicrobials
	Cephalosporins
	Cefamandole
	Cefmenoxime
	Cefoperazone
	Cefotetan
	Trimethoprim-sulfamethoxazole
	Chloramphenicol
	Griseofulvin
	Nitrofurantoin
	Sulfonylureas
	Chlorpropamide
	Tolbutamide
	Chloral hydrate
Genetic	Aldehyde dehydrogenase (ALDH) deficiency

DIFFERENTIAL DIAGNOSIS

Acute altered mental status in the setting of ethanol intoxication must be carefully evaluated for other causes of altered sensorium unrelated to ethanol intoxication. In the appropriate clinical setting, head injuries, CNS infections, and encephalopathy merit consideration as sources of alteration in mental status or cognitive impairment. The differential diagnosis can include hypoglycemia, sepsis, drug or other toxin exposures, carbon monoxide poisoning, Wernicke–Korsakoff syndrome, tumors, blunt traumatic injury,

meningitis, epidural or subdural hematoma, subarachnoid hemorrhage, and dementia, among others. Ethanol abuse typically increases the risk for trauma, illness and these may occur concomitant to ethanol intoxication or as a result of ethanol intoxication. Coingestion of other sedating drugs also may contribute to more pronounced CNS depression (see Chapters 307–310). There is always the danger that a chronic ethanol abuser may substitute ethanol with other potentially lethal intoxicants particularly when deprived of access to ethanol. These other toxic alcohols (see Chapters 299 and 300) may create similar signs and symptoms of inebriation, however a failure to recognize the separate and unique toxicities of these agents may result in renal, visual, and other negative consequences for the patient.

EMERGENCY DEPARTMENT EVALUATION

Obtaining an accurate and thorough history may be impossible when a patient is acutely intoxicated. A thorough medical and surgical history should be sought when possible. In the lucid and cooperative patient, information such as the type, amount, and time of last ethanol use should be obtained. Additional information from friends, family members, or witnesses may be helpful in assessing the risk for trauma, other organ system involvement, presence of medical or psychiatric comorbidities, and potential coingestants.

The initial evaluation of the acutely intoxicated patient or chronic alcohol abuser is identical to the evaluation of any other potentially ill patient. Patients with altered mental status require bedside fingerstick blood glucose determination. A complete set of vital signs, including core temperature and oxygen saturation should be obtained and continuously monitored or frequently reassessed especially if respiratory depression is possible. The patient should be disrobed and carefully examined for signs of trauma or other medical illnesses. During initial evaluation, signs of head trauma, pupil size, appropriate response to voice, hemotympanum, and tenderness to any palpation should be noted. Signs of trauma or coexistent pathology may become more apparent as the patient

becomes less intoxicated. Patients with abnormal vital signs, cardiorespiratory complaints, chest or abdominal pain, or nonspecific constitutional symptoms should have continuous electrocardiographic monitoring and consideration of a 12-lead electrocardiogram (ECG) to evaluate for ischemia and dysrhythmias, particularly atrial fibrillation. Particularly in patients who are unable to offer a medical history, clinicians must be vigilant when performing a physical examination and consider other diagnostic adjuncts such as computed tomography (CT) of the head or abdomen and laboratory testing in unstable patients. Finally, if the clinical examination fails to improve as expected, clinicians should assess for the presence of associated pathology.

Determination of ethanol concentrations in the setting of otherwise uncomplicated acute ethanol intoxication remains controversial. Clinical sobriety may occur in ethanol tolerant individuals at blood-alcohol concentrations that are elevated. In addition, alcohol withdrawal may occur in some tolerant individuals at these elevated blood-ethanol concentrations. Some clinicians do not find ethanol blood or breath concentrations to be helpful in determining patient disposition and avoid levels that may be misinterpreted in potential medical-legal proceedings. Because ethanol intoxication can mimic as well as mask disease and injury, other clinicians argue that obtaining a blood- or breath-ethanol level may aid in estimating the contribution of alcohol in all patients with systemic complaints. Breath-alcohol levels may be helpful in confirming the presence of ethanol; however, accurate sampling is dependent on patient cooperation with obtaining a satisfactory end-expiratory sample. A number of medications contain ethanol and may result in spurious values of the breath-ethanol level. Multidose inhalers, mouthwashes, some gel and foam sanitizers contain significant amounts of ethanol, and sampling of mouth air after vomiting may transiently cause elevations of ethanol concentration. The absence of ethanol or a low ethanol level on breath testing may prompt a search for other conditions that may mimic ethanol intoxication. An accurate blood-ethanol level may help the clinician estimate a reasonable time for observation while the patient

metabolizes the absorbed dose and in the appropriate clinical scenario, additional laboratory or radiographic studies may be avoided. Comatose patients with lower blood-ethanol levels than expected for the level of consciousness may therefore be considered for more extensive diagnostic evaluation that may include CT of the head and lumbar puncture, especially if signs of trauma or infection are present. Because chronic ethanol consumption is associated with both trauma and coagulopathies, the threshold for obtaining head CTs should be low in patients with chronic ethanol use or abuse.

KEY TESTING

- Bedside blood glucose determination with altered sensorium
- Breath- or blood-ethanol concentration
- Electrolytes including calcium and magnesium
- Osmol gap in patients with metabolic acidosis, elevated lactate, low or undetectable ethanol concentration in the setting of profound inebriation or if methanol, ethylene glycol, or isopropanol intoxication is suspected
- Low threshold for brain imaging (CT head) in patients with head trauma and history of chronic alcohol use

Other blood tests may be helpful in the evaluation and treatment of the alcohol intoxicated patient. A rapid point-of-care blood glucose test, complete blood count, electrolytes, blood urea nitrogen (BUN), creatinine, ketones, acetone, lipase, aspartate (AST) and alanine (ALT) aminotransferases, international normalized ratio (INR), ammonia, calcium and magnesium should be considered. The decision to obtain these tests will depend upon specific clinical scenarios and should be guided by patient history and physical examination. An anion gap metabolic acidosis and elevated serum ketones may signify acute alcoholic ketoacidosis (AKA) and warrants measurement of serum osmolality and calculation of the osmol gap. If available, measurement of serum β-hydroxybutyrate concentration may be useful to diagnose AKA (7). The contribution of ethanol to the osmolality can be estimated by dividing the serum

ethanol level in milligrams per deciliter by 4.6. *The formula for calculating Osmol Gap = measured serum osmolality – calculated osmolarity – measured serum ethanol concentration /4.6.* (For further discussion on the osmol gap see Chapters 299 and 300.)

Ethanol-like intoxication in a patient with an osmol gap unexplained by the amount of ethanol present should raise suspicion of acetone, isopropanol, methanol, or ethylene glycol ingestion and should prompt measurement of these agents; however, the absence of an osmol gap cannot exclude the presence of a toxic alcohol, particularly in the case of ethylene glycol.

Chronic alcoholism itself can be difficult to diagnose. Laboratory abnormalities have been linked to chronic alcohol intake, but sensitivities and specificities vary from study to study. γ-Glutamyltransferase, the most sensitive indicator of hepatic injury, rises in patients who have had more than five drinks a day for several weeks. An elevated red blood cell mean corpuscular volume (MCV) may also indirectly hint at protracted ethanol ingestion (Table 297.3).

TABLE 297.3
Laboratory and Radiographic Evaluation

Laboratory	Radiographic
Complete blood count	Chest radiograph
Cell counts for evaluation of marrow function	Pneumonitis
Indices for folate, iron, pyridoxine, B_{12} deficiencies	Aspiration
Serum chemistries	Tuberculosis
Anion gap	Pneumothorax
Hypoglycemia or hyperglycemia	Fractured ribs/trauma
Renal failure	Cardiac size
Electrolyte imbalance (Na, K, Mg, Ca)	Abdominal radiograph
Hypophosphatemia	Pancreatic calcifications
Hyperphosphatemia	Free air
β-hydroxybutyrate	Limb radiograph
Arterial blood gas with carbon monoxide oximetry	Fractures
Hypoxemia	Dislocations
Hypercarbia	Osteomyelitis
Metabolic disturbances	Foreign bodies
Carbon monoxide exposure	Spine radiographs
Anticonvulsant drug levels	Fractures
Urinalysis	Dislocations
Crystalluria	Instability
Myoglobinuria	Computed tomography
Hemoglobinuria	Extra-axial hemorrhage
Liver function tests	Intracerebral hemorrhage
GGT elevation	Intracerebral contusion
AST elevation	Cervical spine injuries
ALT elevation	
Intra-abdominal pathology	

GGT, γ-glutamyltransferase; AST, aspartate aminotransferase; ALT, alanine aminotransferase.

ED MANAGEMENT

As with all patients with acute mental status changes, rapidly reversible causes such as hypoglycemia, hypoxia, and opioid intoxication should be identified and addressed. Supplemental oxygen should be administered if the patient is hypoxic. Intravenous naloxone, thiamine and dextrose should be administered as indicated. Abnormal vital signs should be noted and stabilized. If trauma is suspected, cervical spinal immobilization and

radiographic imaging may be indicated until the patient is sober and can cooperate with a thorough clinical examination. Agitated or combative patients should be restrained with physical and pharmacologic interventions such as intravenous or intramuscular benzodiazepines or butyrophenones such as haloperidol or droperidol. Caution should be exercised with benzodiazepines as they may act additively with ethanol in the depression of respiratory function. Repeated assessments should be performed to assess for clinical deterioration. Patients who do not demonstrate an appropriate improvement in mental status as they metabolize the absorbed ethanol should be considered for further investigation and therapeutic interventions such as airway management. Intravenous fluids, caffeine, coffee, naloxone, or flumazenil have not been demonstrated to reverse the effects of ethanol or promote more rapid elimination (8).

Treatment of DERs is also supportive. Intravenous crystalloids should be administered. Antiemetics can be given for nausea and vomiting. Antihistamines such as diphenhydramine (H_1 subtype) may help alleviate cutaneous flushing. Benzodiazepines may be helpful in alleviating associated anxiety and dysphoria. Most DERs can be managed in the ED. Patients can be discharged once they become asymptomatic and vital signs normalize, provided there are no cardiac complications or further evaluation of chest complaints is not indicated.

Chronic alcoholics who are malnourished or suspected of Wernicke encephalopathy should receive intravenous thiamine 100 mg, as well as hydration with a balanced electrolyte solution containing dextrose. Significant cost savings is possible with oral repletion, and those who are frequent ED patients do not need to receive vitamins on every visit. Concomitant medical or surgical problems are treated through standard measures, and treatment of ethanol withdrawal (Chapter 298) may be required.

CRITICAL INTERVENTIONS

- Test for and treat hypoglycemia.

- Frequently reevaluate to assure a clinical course consistent with uncomplicated intoxication.
- If level of consciousness is not consistent with the ethanol level, consider alternative explanations including infection, metabolic disturbances, trauma, and cointoxicants.
- Administer thiamine to alcoholic patients with altered mental status, cerebellar ataxia, or cranial neuropathy.
- Advise or arrange for counseling or detoxification in patients with suspected alcohol abuse or dependence.

DISPOSITION

A patient with uncomplicated intoxication can be discharged after a period of observation when the patient is deemed clinically sober enough to walk with a stable gait, make sound decisions, and provide self-care. Because clinical sobriety does not correlate with measured ethanol levels, particularly in tolerant patients, a repeat ethanol level is not necessary before discharge. Serial assessments of cognitive and neurologic function should occur however to avoid premature discharge of a patient who is still clinically intoxicated. When a safe destination with a responsible adult is available, discharge may be considered for a patient who is still clinically intoxicated but otherwise stable and improving with intact protective reflexes. Such patients should not be discharged until after an appropriate medical evaluation has been completed. Prior to discharge, the patient should be offered available social assistance, medical follow-up, and referral to detoxification programs.

Indications for hospitalization include prolonged and inappropriately depressed mental status, metabolic derangements not correctable in a timely manner, persistently abnormal vital signs, associated major trauma, severe withdrawal, mixed overdose, and concomitant medical processes such as GI bleeding, pancreatitis, pneumonia, or severe acute hepatitis. A lower threshold for admission should be applied to those patients who are homeless, lack social support or who have baseline organic brain

syndromes that may be related to chronic ethanol abuse. If the patient is admitted, the potential for ethanol withdrawal (Chapter 298) needs to be anticipated, and therapy with benzodiazepines should be provided in the appropriate clinical setting.

Common Pitfalls

- Failure to consider medical, psychiatric, and traumatic conditions in the ethanol intoxicated patient.
- Failure to obtain a blood- or breath-alcohol concentration when the history is unclear or inconsistent with clinical findings.
- Failure to obtain a complete set of vital signs and to fully undress and examine the alcoholic patient.
- Failure to reevaluate the patient frequently and prior to discharge.
- Failure to refer intoxicated patients for counseling or detoxification.

CHAPTER 298 Ethanol Withdrawal

Mark Su

Alcohol is the most commonly abused drug in the world. Alcohol abuse is the third leading lifestyle-related cause of death in the United States and the economic cost associated with alcohol use is estimated to be in the hundreds of billions of dollars (1,2). The effects of alcohol and its association with clinical syndromes are well known (see Chapter 297). However, problems associated with acute alcohol abstinence and alcohol withdrawal require particular attention. Most ethanol-dependent patients typically present to the emergency department (ED) for another reason but develop "alcohol withdrawal" during the course of their management. Recognizing the various clinical manifestations of the alcohol withdrawal syndromes and their appropriate treatment is important to avoid significant patient morbidity and mortality.

Alcohol is a sedative–hypnotic that has multiple effects on the central nervous system (CNS). As with other sedative–hypnotic agents, the inhibitory tone increased by alcohol is mediated via gamma-aminobutyric acid (GABA). With chronic alcohol use, the GABA receptors undergo downregulation, leading to the development of tolerance. *Tolerance* is the pharmacologic effect whereby either increasing doses or increasing frequency of alcohol intake is required to achieve the same physiologic effect. Tolerance to alcohol is necessary for withdrawal to occur. *Dependence* is the altered physiologic state resulting from chronic alcohol use and is also a prerequisite for withdrawal. Continued alcohol use is also associated with inhibition of the excitatory glutaminergic pathways and subsequent upregulation of the *N*-methyl-D-aspartate (NMDA)

receptors. When alcohol intake is abruptly stopped, the result is excess excitatory tone and sympathetic stimulation. This is in large part due to decreased inhibition (GABA effects) and increased excitation (glutamate effects), although the exact mechanism has not been fully elucidated. Decreased dopaminergic activity during acute withdrawal may contribute to hallucinations (3).

CLINICAL PRESENTATION

Alcohol withdrawal presents with a wide spectrum of clinical signs and symptoms. For classification purposes, there are four distinct withdrawal syndromes: *(1) Alcoholic tremulousness, (2) alcoholic hallucinosis, (3) alcoholic withdrawal seizures, and (4)delirium tremens* (4). The first three of these clinically distinct entities may occur in isolation, or simultaneously, in any combination (Fig. 298.1).

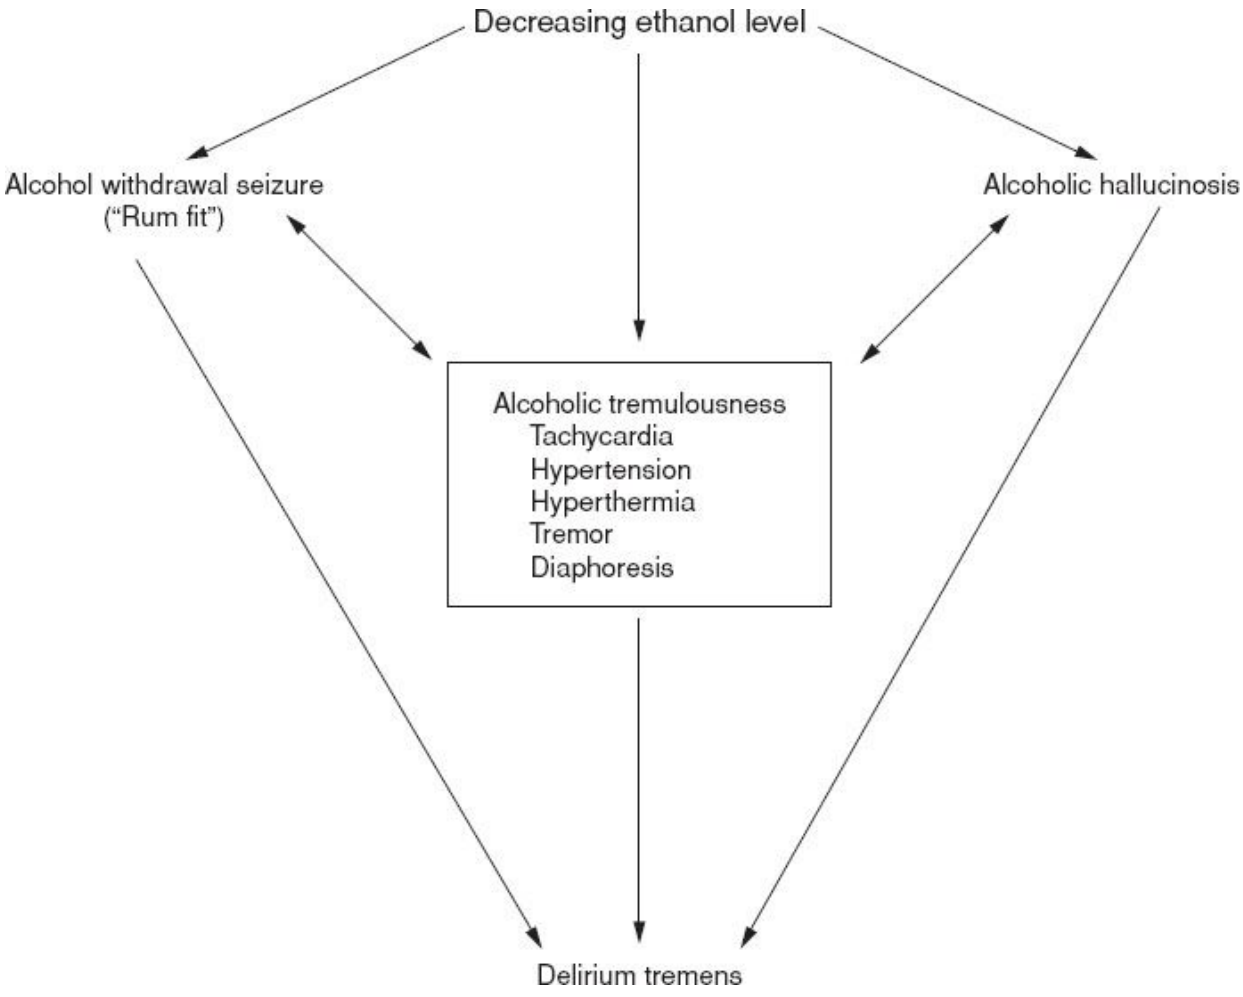

FIGURE 298.1 Adapted from Goldfrank's *Toxicologic Emergencies*. 7th ed.

Alcoholic tremulousness is characterized by catecholamine excess as a result of abstinence. Patients present to the ED with hypertension, tachycardia, diaphoresis, tremor, fasciculations, mild hyperthermia, agitation, and insomnia 4). The patient appears to be extremely uncomfortable but usually has a normal mental status. Symptoms may begin as early as 6 hours after the last drink, and most patients will be symptomatic within 24 to 48 hours after the last intake of alcohol (4). Symptoms are delayed up to 7 days in a few patients (4).

Alcoholic hallucinosis is characterized by frequently visual or sometimes auditory hallucinations that may be persecutory in nature. Formication, the sensation of insects or snakes crawling on the skin, may also occur. The onset is often within a few hours of alcohol cessation and can occur with normal vital signs and without any other manifestations of withdrawal (4).

Alcohol withdrawal seizures, or "rum fits," are the acute onset of a single seizure or a brief flurry of seizures that peak within 24 hours after the last drink. Most patients have a single seizure characterized by a brief postictal state; status epilepticus is rare (4). As with alcoholic hallucinosis, other signs of alcohol withdrawal may occur either before or after the seizures. About one-third of patients with seizures who are untreated progress to delirium tremens (4).

Delirium tremens is the most severe form of alcohol withdrawal. It includes all of the manifestations of the acute withdrawal syndrome in combination with delirium. Only 5% of patients with alcohol withdrawal progress to delirium tremens (4). Signs of delirium tremens include extreme autonomic hyperactivity and alteration in sensorium. Delirium tremens usually occurs within 48 to 72 hours after the last drink and has a typical duration of 3 to 7 days (4). In the past, mortality from delirium tremens was 15% to 20% from fluid and electrolyte abnormalities, seizures, and/or infection. Today, the mortality rate is only 5% in properly treated patients (4).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of alcohol withdrawal is extremely broad because of the many clinical manifestations that occur in isolation or simultaneously and the progression of the condition if left untreated. Furthermore, because patients often suffer from other illnesses, the diagnosis of alcohol withdrawal may be initially overlooked. Consequently, it is crucial to be aware of other etiologies that may mimic the spectrum of alcohol withdrawal (Table 298.1).

TABLE 298.1
Differential Diagnosis of Major Withdrawal Symptoms

Tremor	Seizures	Hallucinations	Delirium
Withdrawal	Withdrawal	Withdrawal	Withdrawal
Ethanol	Ethanol	Ethanol	Ethanol
Sedative–hypnotics	Sedative–hypnotics	Sedative–hypnotics	Sedative–hypnotics
Intoxications	Intoxications	Intoxications	Intoxications
Theophylline	Cocaine	LSD	Cocaine
Caffeine	Anticholinergics	Mescaline	Amphetamine
Beta agonists	Phenothiazines	Mushrooms	Phencyclidine
Mercury	TCAs	Peyote	Anticholinergics
Lithium	Theophylline	Phencyclidine	LSD
TCAs	Camphor	Anticholinergics	Infectious
Phenytoin	Isoniazid	Ergot	Meningitis
Metabolic	Phencyclidine	Nutmeg	Encephalitis
Hypoglycemia	Lidocaine	Infectious	Sepsis
Thyrotoxicosis	Organophosphates	Meningitis	Metabolic

ED EVALUATION

The clinical presentation of alcohol withdrawal may be extremely unpredictable and depends on the particular patient. Most alcohol-dependent patients do not intentionally stop drinking without a new medical illness (such as recurrent pancreatitis, head trauma) or social

barrier (such as new homelessness or losing money in a robbery) that prevents continued consumption. Therefore, when patients are identified in alcohol withdrawal, it is crucial to determine the underlying reason for alcohol abstinence.

Patients should have a fingerstick glucose and oxygen saturation measured. A relevant history includes substance abuse, previous withdrawal episodes, and all current and former medications. If possible, family, friends, and prehospital personnel are interviewed to gain additional information. Vital signs, including rectal temperature, are recorded and closely monitored. Examination of the skin, abdomen, eyes, and pulse rate may help to identify a distinct toxidrome (e.g., anticholinergic, sympathomimetic). Attention should be paid to any signs of chronic liver disease or intravenous drug use.

Substance abusers are at high risk for concomitant trauma because they are unstable, at risk for falling, and often possess poor judgment. Consequently, traumatic injury should always be considered, especially in patients with an altered sensorium. Patients should also be evaluated for other complications of ethanol and drug abuse, such as pneumonia, skin abscesses, bacterial endocarditis, acquired immunodeficiency syndrome, pancreatitis, liver disease, ascites, and gastrointestinal bleeding.

Laboratory studies are useful to screen for concomitant illness and may included: complete blood count; electrolytes, glucose, blood urea nitrogen, and serum creatinine; aminotransferases; coagulation studies; and serum ethanol concentration and urinalysis for ketones. Ethanol concentrations are likely to be negligible or low in most patients in withdrawal; however, measurable serum ethanol concentrations in patients experiencing alcohol withdrawal correlate with the severity of symptoms (5). Since withdrawal occurs with a relative decrease in consumption, some patients who always have a high blood ethanol level can still have withdrawal symptoms at a lower level before getting to zero. Patients with delirium tremens, especially without a previous history, may need computed tomography of the brain and, if negative, a subsequent lumbar puncture to rule out organic CNS pathology as the cause of their altered mental status.

KEY TESTING

- There are no specific tests for ethanol withdrawal
  - Screening laboratory testing includes serum chemistry, transaminases, complete blood count, coagulation studies, urinalysis, and ethanol concentration
- Patients with altered mental status may require CT of the brain
- If infection is considered, obtain blood cultures, chest x-ray, and urine culture
- Lumbar puncture may be required to rule out meningitis or subarachnoid hemorrhage

ED MANAGEMENT

In any patient with an altered sensorium, a toxicologic cause is always possible. Intravenous dextrose is indicated if the patient has hypoglycemia (usually <90 mg/dL). Chronic alcohol use is commonly associated with hypoglycemia for several reasons. Alcoholics are often nutritionally depleted and may have insufficient glycogen stores from liver dysfunction. Chronic ethanol use also leads to an impaired redox potential from the accumulation of NADH and subsequent depletion of pyruvate, one of the major precursors of gluconeogenesis.

Thiamine (vitamin B_1) is also considered for patients with an altered sensorium and patients with a history of alcohol abuse because of the possibility of Wernicke encephalopathy (triad of ataxia, dementia or confusion, and ophthalmoplegia). This condition is rare but may occur as a result of nutritional deficiency. Alcoholics have also been shown to be thiamine deficient (6). The standard initial dose of thiamine is 100 mg intravenously. For patients who are known alcoholics and often malnourished, other multivitamin preparations and magnesium sulfate may also be administered, but their benefit is unproven (7).

Intravenous fluids are often necessary and important for the treatment of alcohol withdrawal, because alcohol induces a diuresis and leads to volume depletion (4). Alcohol withdrawal is often due to an underlying medical condition (e.g., pneumonia, pancreatitis,

head trauma) that prevents the usual alcohol intake. These patients may require aggressive volume resuscitation for the treatment of this concurrent condition.

Agitated patients may need soft restraints to prevent injury, facilitate intravenous access, and enhance sedation. Prolonged use of restraints with continued struggling may lead to rhabdomyolysis, hyperthermia, and metabolic acidosis.

The goal of therapy for the agitated alcohol withdrawal patient is sedation. Benzodiazepines, the cornerstone of therapy are sedative–hypnotics, like ethanol, and exert their pharmacologic effect via the GABA receptor (8). Benzodiazepines are usually effective in the treatment of alcohol withdrawal because they possess *cross-tolerance* with alcohol. Nevertheless, some patients require massive doses of intravenous benzodiazepines for adequate sedation. Patients "refractory" to benzodiazepines should be treated with a different GABA agonist, such as a barbiturate (e.g., phenobarbital). Patients with severe refractory alcohol withdrawal, unresponsive to benzodiazepines, may respond to a propofol infusion. Propofol is both a GABA agonist and an NMDA antagonist and is effective in several case reports to treat alcohol withdrawal. Patients who receive barbiturates or propofol are more likely to require airway protection, because of potential respiratory depression.

Symptom-triggered therapy refers to the administration of benzodiazepines when the patient's symptoms exceed a threshold of severity and is given until the patient's symptoms are adequately controlled. This is in contrast to a fixed-dose regimen of a set amount of benzodiazepine at regular intervals with a subsequent taper after the patient's symptoms are under control. The symptom-triggered method is a better technique and decreases the total amount of benzodiazepines administered, the duration of treatment, and the incidence of delirium tremens, as compared to the fixed-dose method (9,10).

Diazepam (Valium), chlordiazepoxide (Librium), and lorazepam (Ativan) are the most common agents for alcohol withdrawal and can also be used for sedative–hypnotic withdrawal. These agents are preferred over benzodiazepines with shorter half-lives because they

require less frequent dosing and allow gradual elimination of the drug over several days.

Long-acting benzodiazepines may be more effective than short-acting agents in preventing withdrawal seizures and can contribute to smoother withdrawal with fewer rebound symptoms (4). The active metabolites of diazepam and chlordiazepoxide prolong their therapeutic effect. In elderly patients and those with hepatic dysfunction, lorazepam may be preferred because it has no active metabolites. In other cases, lorazepam does not appear to offer any distinct advantage over diazepam or chlordiazepoxide (4). See Table 298.2 for dosing recommendations for various benzodiazepines.

TABLE 298.2
Pharmacologic Management of Ethanol Withdrawal

Ethanol or Sedative–Hypnotic Withdrawal
First choice: Diazepam
5-mg IV bolus every 5–15 min until sedated
May increase dose to 20 mg every 5–15 min in refractory cases
Total over 24-hr period may exceed 1,000 mg
If >300 mg given, may consider adding another GABA agent (e.g., barbiturate, propofol)
Do not exceed 5 mg/min
Second choice: Lorazepam
1–2 mg IV bolus every 5–15 min until sedated
Not as long acting as diazepam
Preferable in cases of hepatic failure or recurrent seizures
Third choice: phenobarbital
130 to 160 mg IV bolus
Can repeat every 15–20 minutes
Continue to sedation
Potential for more respiratory depression than benzodiazepines
Do not exceed 50 mg/min
Alternatives
Chlordiazepoxide, secobarbital

Reproduced from *Withdrawal Syndromes in Emergency Medical Clinical Care*. 3rd ed.

In a patient who can tolerate oral medication and is in mild withdrawal, oral benzodiazepines may be sufficient. However,

intravenous dosing of benzodiazepines is faster, more precise and preferred for patients with more severe withdrawal. Agitation may preclude oral administration, and gastritis may impair drug absorption. Intramuscular lorazepam (but not diazepam or chlordiazepoxide) is absorbed predictably and is recommended when intravenous access is not readily obtained. Once symptoms are controlled, several days of oral treatment may be used for maintenance.

Patients who have abstinence seizures should be given standard supportive therapy and benzodiazepines to stop seizure activity. Phenytoin is not effective for treating alcohol withdrawal seizures and should not be given unless the patient has a known seizure focus and was previously taking this drug prior to presentation. Carbamazepine and valproic acid are mildly efficacious in certain settings but have not been studied in an ED setting or in patients with delirium tremens. Consequently, these anticonvulsants are not recommended for patients with significant signs and symptoms of alcohol withdrawal.

Historically, beta-adrenergic antagonists, clonidine, and antipsychotics (phenothiazines and butyrophenones) have been used for the treatment of alcohol withdrawal, but none of these agents exerts its primary effects through GABA. Though they may appear to control symptoms and improve vital signs, their efficacy in improving withdrawal outcomes is not demonstrated, and their routine use is discouraged.

CRITICAL INTERVENTIONS

- Treat alcohol withdrawal early with IV fluids and IV benzodiazepines. Treatment becomes increasingly more difficult as the disease progresses.
- Identify any precipitating illness. Concurrent infection is often the precipitant for ethanol abstinence and subsequent withdrawal.

DISPOSITION

Depending on the particular withdrawal syndrome, the reason for cessation of alcohol, and the severity of alcohol withdrawal signs and symptoms, the disposition of patients with alcohol withdrawal is extremely variable. As long as there are no critical medical conditions that will prevent the patient with mild alcohol tremulousness from resuming normal activities, patients may be safely discharged with treatment and referral to a detoxification program.

Patients with more severe signs and symptoms of alcohol withdrawal, including alcohol withdrawal seizures and alcoholic hallucinosis, will require hospital admission. Patients with delirium tremens will require admission to an intensive care unit for close cardiac and hemodynamic monitoring. Patients who are not adequately sedated with conventional doses of benzodiazepines may require propofol, necessitating intensive care unit admission for respiratory monitoring and subsequent endotracheal intubation, if necessary.

Common Pitfalls

- Overlooking alcohol withdrawal as a potential cause of altered sensorium and autonomic instability
- Failing to recognize and correct metabolic or treat infectious causes of illness in the alcoholic patient
- Using a fixed-dose schedule of benzodiazepines to treat ethanol withdrawal rather than titrating doses to symptoms

CHAPTER 299 Ethylene Glycol

Thomas C. Arnold

Ethylene glycol (EG; 1,2-ethanediol) is a colorless, odorless, sweet-tasting, water-soluble liquid that has a wide variety of household and commercial uses (1). Because of its low freezing point (~13°C) and high boiling point (198°C), EG is commonly used as antifreeze–coolant. Automotive antifreeze contains about 95% EG and is the source of most EG poisonings. EG is also found in adhesives, brake and hydraulic fluids, cosmetics, de-icers, detergents, fire extinguishers, inks, lacquers, paints, pesticides, polishes, and some windshield-washer fluids.

In 2011, poison centers in the United States received reports of 6,277 single exposures to EG, including 18 fatalities. The majority of exposures occur unintentionally through misuse or by accident (2). Intentional ingestion with suicidal intent results in the majority (>75%) of fatalities but accounts for only 15% of EG exposures. In 2011, one fatality was attributed to unintentional exposure to EG (2). Widespread availability probably accounts for its ingestion by alcoholics seeking an ethanol substitute, while its interesting color and pleasant, bittersweet taste make it attractive to children.

Unmetabolized EG produces about the same degree of central nervous system (CNS) depression as ethanol. Other effects (anion gap metabolic acidosis, coma, seizures, cardiopulmonary dysfunction, and acute renal failure) result largely from accumulation of toxic metabolites, that is, glycolic and oxalic acids (1,3,4).

EG is absorbed rapidly from the gastrointestinal tract and distributed throughout total body water (0.6 L/kg). Peak blood

concentration occurs about 2 hours after ingestion (4). About 20% to 50% of EG is excreted unchanged in the urine (4). The remaining EG is metabolized in the liver to a variety of compounds with varying toxicities (eFig. 299.1). EG elimination is first order, with a half-life of 2.5 to 4.5 hours in patients with normal renal function and alcohol dehydrogenase activity (1,4–6).

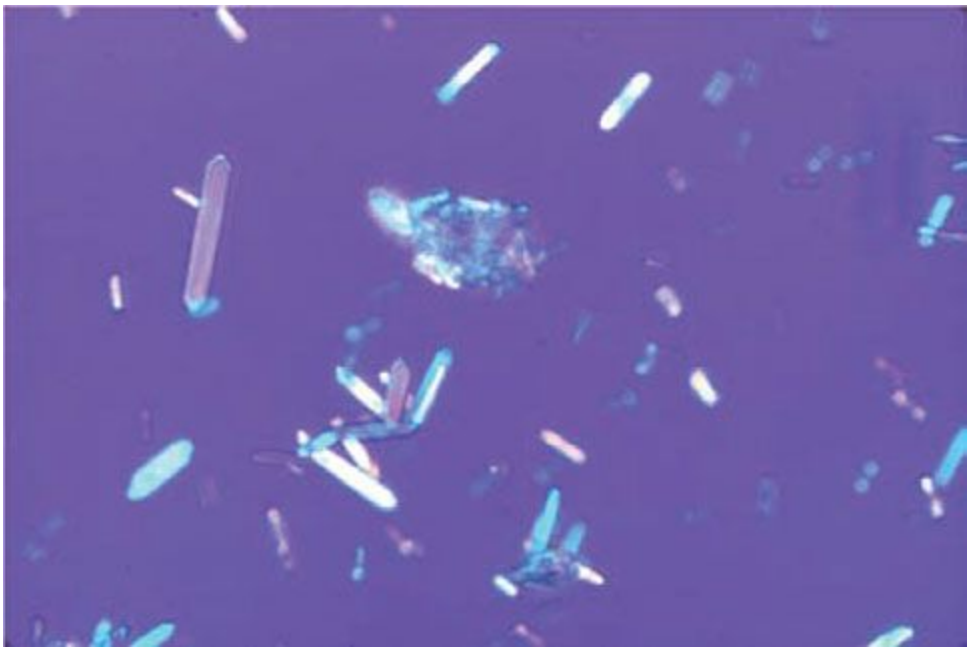

FIGURE 299.1 Calcium oxalate as needle-shaped monohydrate crystals. (From Tilley, DVM, Smith, DVM. *The 5-Minute Veterinary Consult: Canine and Feline*. 3 ed. Lippincott Williams & Wilkins; copyright 2004.)

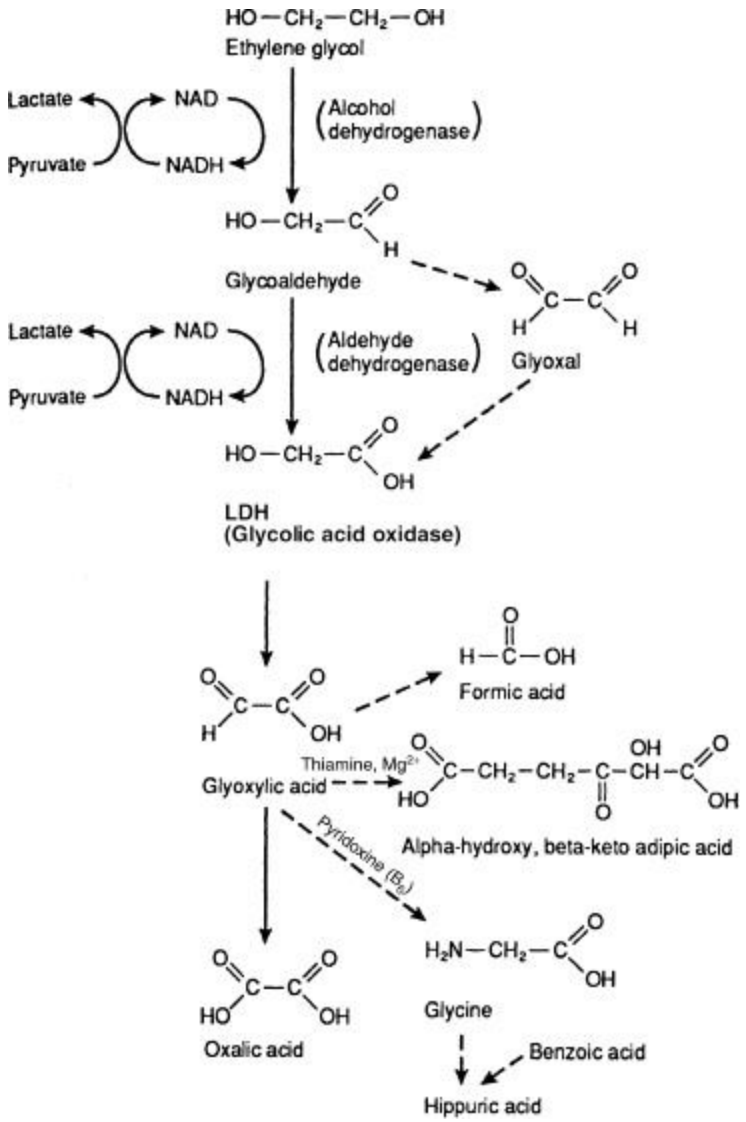

eFIGURE 299.1 Metabolism of ethylene glycol. Solid lines, known pathways of metabolism; dashed lines, postulated pathways of metabolism.

The first step in the metabolism of EG is its oxidation to glycoaldehyde by alcohol dehydrogenase (ADH) (4). Because ADH has a much higher affinity for ethanol and fomepizole (a synthetic ADH inhibitor) than for EG, these substrates are preferentially bound over EG. Their presence inhibits the metabolism of EG sixfold, preventing the formation of toxic metabolites, which is the mechanism of their action as antidotes (1,3,4).

Once formed, glycoaldehyde is metabolized rapidly by aldehyde dehydrogenase to glycolic acid, which is further metabolized slowly by glycolic acid oxidase to glyoxylic acid (1,4). Because this latter step is rate limiting, glycolic acid tends to accumulate (1,3). The level of glycolic acid correlates with the increased anion gap, decreased arterial pH, development of renal injury, and mortality associated with advanced EG poisoning (3,4). Once formed, glyoxylic acid is oxidized rapidly to one of several metabolites. Its principal metabolite, oxalic acid, precipitates as calcium oxalate crystals in various organs and tissues (1,4).

The deposition of calcium oxalate monohydrate crystals is responsible for much of the end-organ injury that results from serious EG poisoning (e.g., nephrotoxicity, meningoencephalitis, and cerebral and pulmonary edema) (1,4). Accumulation of crystals within proximal renal tubules leads to physical blockage and compression of the tubular lumen, direct renal tubular cytotoxicity (cell membrane and oxidative cellular injury), and subsequent development of acute tubular necrosis and renal failure (4). Although some evidence suggests that glycoaldehyde and glyoxylic acid are also nephrotoxic, their contribution to renal tubular injury in EG poisoning is probably negligible because they are metabolized rapidly (1,4).

Significant systemic toxicity from EG occurs only after ingestion (1,4). Skin exposure can cause minor irritation, and direct eye contact can cause conjunctivitis, chemosis, and iridocyclitis. Because of the high boiling point of EG, there is no toxicity from vapor inhalation. The toxic and lethal doses of EG after acute ingestion vary. Because ingestion of just 0.1 mL/kg of pure EG can induce potentially toxic blood concentrations, the ingestion of even a mouthful of the liquid should be considered hazardous. Although the lethal oral dose is approximately 1.5 mL/kg, there is a poor correlation between the amount consumed and prognosis (4,5).

CLINICAL PRESENTATION

EG poisoning manifests in three distinct stages of CNS, cardiopulmonary, and renal involvement. Their onset, progression, and confluence vary widely (1,4). Thirty minutes to 12 hours after ingestion, CNS signs and symptoms predominate, starting with slurred speech, ataxia, nystagmus, and lethargy. The patient may appear intoxicated but instead of the breath odor of ethanol, a faint, sweet, or aromatic odor may be detected. Nausea, vomiting, and abdominal pain might also be present.

After a latent period of 3 to 12 hours, signs and symptoms develop from accumulated toxic metabolites. CNS depression progresses to stupor and coma. Hyperreflexia, tremor, tetany, cranial nerve abnormalities, and seizures (both focal and generalized) may occur. Severe CNS disturbances could reflect the development of cerebral edema and meningoencephalitis (4). In the late stages of poisoning, when most or all EG has been metabolized, measuring the serum glycolic acid level might be the only way to confirm the diagnosis.

Cardiopulmonary signs such as hypertension, tachycardia, dysrhythmias, and pulmonary edema develop 12 to 36 hours after the ingestion of EG. During this stage, compensatory tachypnea and Kussmaul respirations reflect a progressively worsening anion gap metabolic acidosis.

Urinalysis can provide additional evidence of EG poisoning. Proteinuria and microscopic hematuria are seen in more than 60% of cases (3–5). The presence of hematuria and oxaluria is not predictive of acute renal failure (5). Calcium oxalate crystalluria, although nonspecific, is present on admission in more than 40% of patients; this percentage increases with serial urinalysis and delayed presentation (3–5). Calcium oxalate is often excreted as needle-shaped monohydrate crystals (Fig. 299.1), which might be misidentified as hippuric or uric acid crystals (4). At higher urinary concentrations, calcium oxalate is also excreted in an envelope-shaped dihydrate form (Fig. 299.2) (4). The binding of calcium to oxalate may result in hypocalcemia, causing myoclonic jerks or tetanic contractions (1,4). Because fluorescein is added to many commercial antifreeze preparations, fluorescence of urine or gastric

contents with a Wood lamp supports EG poisoning early after ingestion. Fluorescence is insensitive and nonspecific, however, and cannot be relied on to make or exclude the diagnosis of EG poisoning.

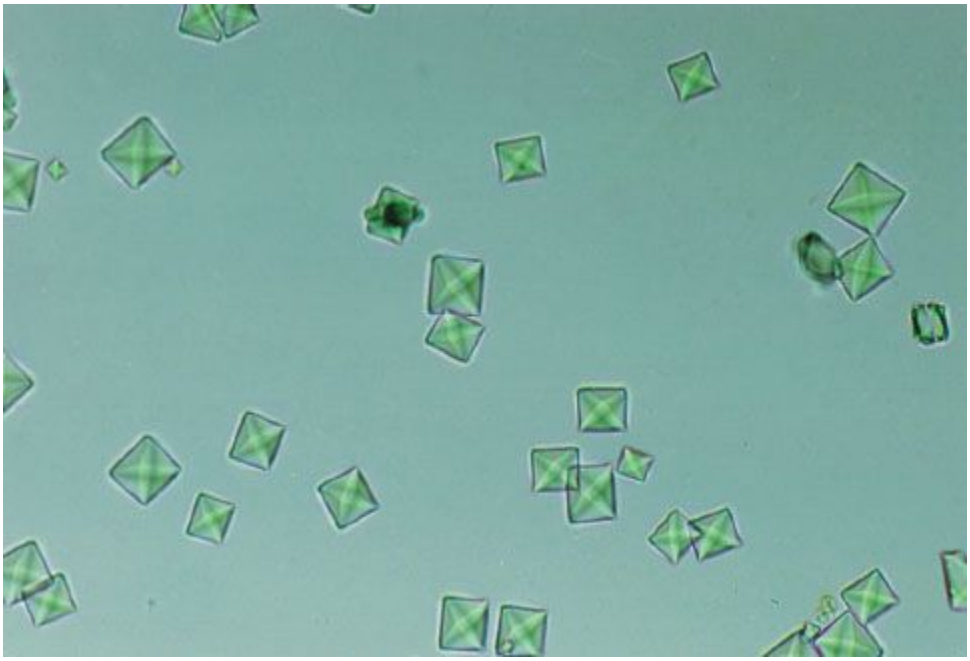

FIGURE 299.2 Calcium oxalate as envelope-shaped dihydrate crystals. (McClatchey KD, M.D., D.D.S. *Clinical Laboratory Medicine*. 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2002.)

EG plasma concentrations do not correlate with mortality (5). Rapid diagnosis and treatment prevent EG bioactivation and lethality, regardless of the initial plasma EG concentration (7). Severity of illness is best predicted by the degree of anion and osmolal gap. Patients with anion gaps less than 20 and osmolal gaps less than 25 usually survive (7). Death results from cerebral edema and infarction, multiple organ failure, and irreversible shock (1,4). Even with treatment, the mortality rate is 5% to 17% (3).

Renal dysfunction (seen in nearly 70% of cases) is characterized by oliguria, proteinuria, and urine with a low-specific gravity and sodium content (acute tubular necrosis). Some patients complain of severe flank pain (1,4). Renal dysfunction may be noted as early as 9 hours after ingestion (3). The high frequency of renal injury may

be attributed to delayed presentation or delayed diagnosis and treatment (5). The degree of metabolic acidosis or glycolic acid accumulation at the initiation of treatment, rather than EG plasma concentration, correlates closely with the subsequent development of renal injury (3–5). In one retrospective study, an initial glycolic acid level >8 mmol/L, an anion gap >20 mmol/L, or an arterial pH <7.30 was highly predictive of acute renal failure (5). Conversely, acute renal insufficiency is unlikely to develop in patients who have an initial glycolic acid level <8 to 10 mmol/L, an arterial pH >7.30, or normal renal function upon initiation of appropriate treatment (3,5). Although most treated patients have a complete recovery, some may have protracted renal insufficiency requiring months of hemodialysis.

Cranial nerve deficits (usually VII nerve dysfunction), basal ganglia and brainstem infarction, parkinsonism, and cerebral edema are rare but possible consequences of EG poisoning. They can present as long as 3 weeks after acute poisoning (1,4,8).

DIFFERENTIAL DIAGNOSIS

EG intoxication can mimic a large variety of poisonings or disease states, depending on the amount ingested and the degree of its metabolism at presentation. Diagnostic clues include drunken behavior without the odor of ethanol, a delay between ingestion and significant illness, hyperventilation on physical examination, increased osmolal or anion gap, metabolic acidosis, calcium oxalate crystalluria, and hypocalcemia. The differential diagnosis includes alcoholic, diabetic, and starvation ketoacidosis; lactic acidosis; renal failure; methanol poisoning; and advanced, untreated acetaminophen or salicylate poisoning. If the history does not suggest lactic acidosis or ketoacidosis, a high osmolal gap with anion gap metabolic acidosis strongly points toward EG or methanol poisoning (4). In methanol intoxication, crystalluria is absent, and the patient might report visual disturbances or have abnormal results on eye examination. Although a large osmolal gap (particularly >25) suggests toxic alcohol poisoning, a small gap

(<10) cannot be used to exclude significant EG poisoning, particularly in the later stages of poisoning, when significant metabolism has already occurred (1,4,5). Disorders of inborn organic acid metabolism should be considered in the differential diagnosis of young children with an increased anion gap metabolic acidosis.

ED EVALUATION

The history should include the time of ingestion; the volume and concentration of the ingested product; and the onset, nature, and progression of symptoms. The intent of the ingestion, accidental versus intentional, should be ascertained, since intentional ingestions are often more serious. The ingestion of other substances, particularly ethanol, should be documented. Patients should be asked specifically about ethanol-like intoxication, shortness of breath, flank pain, and urinary dysfunction.

The physical examination should focus on neurologic status, cardiopulmonary function, and any abdominal and back tenderness. In children or unreliable adults, fluorescein staining of the mouth or clothes can provide a clue to the exposure.

Laboratory evaluation is critical and should include urinalysis (UA) (specify crystal analysis) and quantitative serum EG concentration by gas chromatography and mass spectrometry (GC/MS) to confirm the diagnosis. In early stages and where EG levels are not available, measuring serum osmolality along with serum electrolytes, blood urea nitrogen, creatinine, glucose, serum ethanol can determine an elevated osmolal gap which may be a clue to the diagnosis of EG poisoning (4,5). Because of its low molecular weight (62 g/mol), only high concentrations of EG increase the serum osmolality appreciably. This increase in osmolality elevates the osmolal gap, the difference between the serum osmolality measured by the freezing-point depression (but not the vapor pressure method) and the calculated osmolarity ([2 × sodium] + [glucose/18] + [blood urea nitrogen/2.8] + [serum ethanol concentration/4.25]). Note that ethanol is osmotically active (1

mOsm for each 4.25 mg/dL of serum ethanol) and must be subtracted (4,5,9). Normally, serum osmolality ranges from 280 to 300 mOsm/kg H_2O, with a normal osmolal gap of –2 ± 6 mOsm/kg. If EG analysis is not readily available, the serum level (milligrams per deciliter) can be estimated roughly by multiplying the osmolal gap by 6.2 (mg/dL per mOsm of EG). The osmolal gap is not precise enough to make a diagnosis, but a very large osmolal gap is strongly suggestive.

A decrease in the serum bicarbonate concentration and an increased anion gap metabolic acidosis may be seen as early as 3 hours after EG ingestion (1,3). The normal anion gap (serum sodium minus chloride and bicarbonate), representing unmeasured anions in the serum, is 12 ± 2 mEq/L. In EG poisoning, glycolic acid accounts for a large part of the unmeasured anions. The absence of metabolic acidosis is consistent with an early presentation, an insignificant ingestion, or the coingestion of ethanol, which blocks the metabolism of EG. Measuring blood gas, ketones, lactate can help determine other causes of acidosis.

Because many antifreeze products contain methanol or propylene glycol, serum concentrations of these agents should be ordered if the identity of the ingested substance cannot be confirmed. Occasionally, glycolic acid quantification by special GC/MS techniques is necessary for patients who present very late (e.g., with renal failure and no detectable EG) (3,5).

KEY TESTING

- Early presenting patients should have EG levels, UA, laboratories to determine osmolal gap and a baseline blood gas analysis.
- In addition, late presenting patients and those waiting for EG levels to return should have calcium, blood gas analysis, lactate, and ECG.

ED MANAGEMENT

Airway protection and respiratory and circulatory support, with cardiac and hemodynamic monitoring, should be instituted as

necessary. Intravenous fluids should be administered liberally at first to maintain adequate urine output; a large urine flow increases the excretion of EG in patients not in renal failure (4). If the patient intentionally ingested EG only shortly before presentation, gastric aspiration via a nasogastric tube should be performed immediately. Activated charcoal adsorbs EG but might be clinically ineffective because EG is absorbed rapidly and the capacity of charcoal to bind EG is exceeded when moderate amounts of EG are ingested. Activated charcoal is recommended if a coingestant is suspected. Most accidental exposures involving a single swallow or two will probably not benefit from gastric decontamination.

Specific treatment for EG poisoning consists of sodium bicarbonate to correct metabolic acidosis, calcium to correct symptomatic hypocalcemia, ethanol, or fomepizole to inhibit production of toxic metabolites, hemodialysis to remove EG and its toxic metabolites, and cofactors (e.g., magnesium, pyridoxine, and thiamine) to enhance endogenous clearance of toxic metabolites (1).

Correction of metabolic acidosis might require large amounts of intravenous sodium bicarbonate ($NaHCO_3$):

$$NaHCO_3 \text{ dose} = 0.7 \times \text{kg} \times (24 - \text{actual } [HCO_3^-])$$

where 0.7 is the volume of distribution of bicarbonate in acidemia, kg is the lean body weight, and 24 is the desired $[HCO_3^-]$. $NaHCO_3$ should be given in 1-mEq/kg increments (1,4). Increasing the serum pH increases the fraction of ionized acid metabolites, thereby minimizing their tissue redistribution and maximizing their renal clearance through ion trapping. The patient's acid–base status should be reevaluated frequently to assess the response to therapy. Hypocalcemia could be worsened by sodium bicarbonate administration (1,4).

Serum calcium levels should be monitored frequently. Symptomatic hypocalcemia (e.g., cardiac dysrhythmias, tetany, and seizures) should be treated with intravenous calcium chloride or gluconate (7 to 14 mEq for adults and 1 to 7 mEq for children). The 10% calcium chloride solution contains 1.4 mEq of calcium per

milliliter, and a 10% calcium gluconate solution contains 0.46 mEq/mL. Calcium is not recommended for patients with asymptomatic hypocalcemia, as its administration could increase calcium oxalate tissue precipitation and overall EG toxicity. Seizures should be treated with standard drugs (diazepam, lorazepam, or a barbiturate).

Traditionally, ethanol has been used to inhibit the alcohol-dehydrogenase–mediated metabolism of EG. Fomepizole (4-methylpyrazole, 4-MP; Antizol) is a potent, long-acting, competitive alcohol dehydrogenase inhibitor that is a safe, easy, and effective alternative to ethanol (1,3,4,6). Unlike ethanol, fomepizole is approved by the US Food and Drug Administration (FDA) for the treatment of EG and methanol poisoning. In humans and animals poisoned by EG, fomepizole attenuates and prevents metabolic acidosis and renal failure by halting the accumulation of glycolic and oxalic acids, respectively (1,3,5). Fomepizole has higher potency, longer duration of action, more predictable kinetics, and an easier dosing regimen than ethanol (1,3,5) and does not require frequent monitoring and adjustment of plasma concentrations. In addition, fomepizole does not produce the CNS depression, hypoglycemia, gastritis, pancreatitis, fluid overload, and habituation commonly associated with ethanol therapy (1,3,6,8). Fomepizole is generally safe in humans, although it has been associated with dizziness, eosinophilia, headache, nausea, rash, transient hepatic transaminase elevation, phlebitis, and seizures (1,3,6,8). The higher cost of fomepizole (~$1,000 US per 1.5-g vial) is balanced by greater patient safety and the lower costs of less patient monitoring and fomepizole has become preferred over ethanol in the United States. In 2011, poison centers received 2,053 reports of its use compared with 91 reports of ethanol use (2). Fomepizole has not been studied specifically in the children but one review of published literature suggests fomepizole is effective and well tolerated in children when given in the normal adult dosages (10). Fomepizole is labeled pregnancy category C by the FDA and therefore is recommended for use during pregnancy only when the benefit

outweighs the risk. It is contraindicated in patients who are allergic to pyrazole derivatives.

Both ethanol and fomepizole bind alcohol dehydrogenase preferentially over EG, which prevents the further metabolism of EG to its toxic metabolites so that EG can be eliminated by urinary excretion or hemodialysis. Indications for treatment with ethanol or fomepizole include a measured serum EG concentration >20 mg/dL; a documented history of significant recent EG ingestion when a serum EG concentration is not immediately available (particularly if the osmolal gap is elevated); or strong suspicion of EG ingestion based on abnormal clinical or laboratory findings (e.g., unexplained anion gap metabolic acidosis, elevated corrected osmolal gap [or both], or oxalate crystalluria) (1,3,4).

For fomepizole, a loading dose of 15 mg/kg IV should be followed by doses of 10 mg/kg IV every 12 hours thereafter (3). All doses are diluted in 100 mL of 5% dextrose in water or normal saline and administered by slow IV infusion over 30 minutes (2,8). Like ethanol, fomepizole is effective when orally administered but this route has not been fully studied or approved (1). Fomepizole is continued until the EG concentration falls below 20 mg/dL (3).

For ethanol therapy, the therapeutic goal is a serum ethanol concentration of at least 100 mg/dL, which is sufficient to prevent metabolism of EG even at high concentrations (4). IV administration is preferred, because it achieves a more rapid and constant serum concentration (1,4). Administration of an IV loading dose of 10 mL/kg of 10% ethanol (preferably in a glucose-containing solution, such as D_5W, to avoid hypoglycemia) over 30 to 60 minutes, followed by a maintenance infusion of 1.5 mL/kg/hr, generally produces a serum ethanol concentration of slightly >100 mg/dL (4). Alternatively, 5 mL/kg of 20% (40 proof) ethanol can be administered orally or via nasogastric tube to achieve the desired loading dose; the hourly maintenance oral dose is similar to that for IV administration (1.5 mL/kg/hr of 10% ethanol) (1,4). Mental status, serum ethanol and glucose concentrations should be

monitored and the dose of ethanol adjusted, as necessary, to maintain a therapeutic ethanol concentration.

Hemodialysis rapidly removes both EG and glycolic acid (4,5). Elimination half-lives are reduced to approximately 3 hours for each, compared with 19 and 10 hours, respectively, with alcohol dehydrogenase inhibitor therapy alone (1,3,6). Indications for hemodialysis include significant metabolic acidosis (arterial pH <7.30), renal insufficiency (serum creatinine >1.2 mg/dL), or deterioration in these parameters or clinical status despite conventional treatment (1,3–5).

Traditionally, hemodialysis has been recommended for patients with a serum EG concentration of 50 mg/dL or greater (4). However, this concentration does not define toxicity, predict prolonged elimination, or correlate with patient outcome. Recent evidence suggests that patients who present before the development of metabolic acidosis and renal impairment can be managed effectively and safely with fomepizole monotherapy (i.e., without hemodialysis) regardless of the initial EG concentration (1,3,5). In these patients, EG is excreted by the kidneys, with an approximate half-life of 18 hours (1,3,5,6). For patients who present with elevated serum creatinine, however, EG elimination half-life is prolonged to approximately 49 hours, and hemodialysis is recommended (3,6). These patients will also likely require hemodialysis based on the presence of a significant metabolic acidosis. Hemodialysis should be continued until acid–base and metabolic abnormalities are corrected and serum EG concentrations are below 50 mg/dL (3,4).

The infusion rate of ethanol should be increased to 3 mL/kg/hr during hemodialysis to compensate for increased clearance (1,4). Because fomepizole is also dialyzable, it should be administered by a continuous IV infusion of 1 to 1.5 mg/kg/hr or its dosing frequency increased to every 4 hours during hemodialysis (3). If hemodialysis is unavailable or technically difficult (e.g., in infants), peritoneal dialysis can be used, although this method is considerably less effective than hemodialysis.

Pyridoxine, thiamine, and magnesium are cofactors in the metabolism of EG to less toxic products (see eFig. 299.1). Their administration could preferentially shunt metabolism of glyoxylic acid away from oxalic acid. Both pyridoxine and thiamine are given intravenously in doses of 100 mg four times daily (4).

CRITICAL INTERVENTIONS

- Administer fomepizole or ethanol to patients with signs, symptoms, or laboratory evidence of EG poisoning.
- Administer IV sodium bicarbonate to patients with acidemia.
- Arrange hemodialysis for patients with EG poisoning that is severe or refractory to other treatment.

DISPOSITION

Patients with significant EG poisoning require admission to an intensive care unit. The need for hemodialysis should always be anticipated, and transfer to a facility with that capability should be considered if such treatment is unavailable in the initial treating hospital. Patients who have ingested only a small volume of EG accidentally and do not develop acidosis or have toxic levels of EG can be discharged.

Common Pitfalls

- Failure to consider EG as a cause of ethanol-like intoxication and increased anion gap metabolic acidosis.
- Failure to appreciate that a normal osmolal or anion gap does not exclude the presence of potentially toxic amounts of EG.
- Failure to observe and monitor all patients with known or suspected ethylene EG ingestion until an EG level can be obtained or until the time of expected toxicity has passed without incident.
- Failure to appreciate the importance of fully correcting acidemia.
- Failure to appreciate that ethanol and fomepizole are removed by hemodialysis and to increase their dosing accordingly during this procedure.

CHAPTER 300 Methanol

Thomas C. Arnold

Methanol (methyl alcohol, “wood alcohol”) is a clear, colorless, highly flammable liquid at room temperature. It is less dense than water (0.81 g/mL) and has a faint odor resembling ethanol. Methanol is a widely used industrial solvent in the production of formaldehyde and methylated compounds. It is found in many commercial products such as gasoline, antifreeze, windshield washer fluid, copy machine fluid, canned heat (Sterno), stains, paint thinners, varnishes, and wood refinishing solvents. Poisoning easily occurs after the accidental or intentional ingestion of such products. In 2011, poison centers in the United States received reports of 1,711 methanol exposures, 9 of which resulted in death (1). Although most cases are isolated, epidemics of poisoning can occur when methanol is mistakenly substituted for ethanol or when it contaminates alcoholic beverages such as wine or moonshine whisky.

Methanol is absorbed within 30 to 60 minutes after ingestion and is water soluble. It can penetrate the skin to some degree and is slightly volatile. For these reasons, toxicity after extensive dermal contact and inhalation has been reported (2). The volume of distribution approximates total body water, at 0.6 L/Kg. The metabolism of methanol to formaldehyde by alcohol dehydrogenase follows zero-order kinetics and accounts for 90% of its elimination. Small amounts are also excreted in expired air and urine. Formaldehyde is rapidly metabolized to formic acid, which is responsible for the toxic effects of methanol (Fig. 300.1) (3). The metabolism of formate is dependent on folate stores. Primates have a

small folate reserve and are the only species that accumulates formate and susceptible to methanol toxicity (3).

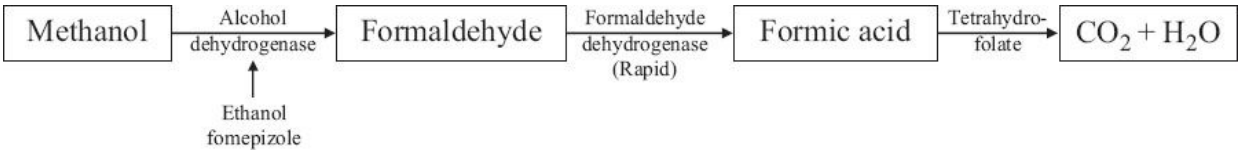

FIGURE 300.1 Methanol metabolism.

Early in poisoning, toxicity is caused by the central nervous system (CNS) depressant effect of methanol and metabolic acidosis caused by formic acid accumulation (3). Later, the toxicity is caused mainly by the histotoxic effects of accumulated formate, which inhibit mitochondrial respiration. This results in lactate production, worsening acidosis, and increased penetration of the blood–brain barrier by formate as it becomes protonated. The eye and basal ganglia are the primary targets for methanol's toxic effects; the reason is not known (3,4). The lethal dose of methanol is reported variably as 30 to 240 mL, with 1 g/kg (1 g = 1.2 mL) considered the best estimate (3). The minimum dose that causes permanent visual defects is unknown.

Ethanol and fomepizole bind to alcohol dehydrogenase with a higher affinity than methanol and hence block the production of toxic metabolites. Ethanol is metabolized by alcohol dehydrogenase, but fomepizole is not. When these antidotes are used, the elimination half-life of methanol increases from 24 hours to as long as 60 hours (3,5).

CLINICAL PRESENTATION

In most cases, 6 to 24 hours elapse from the time of ingestion to the emergence of symptoms. This period of time is required for a sufficient amount of formic acid to be produced by methanol metabolism. A latent period up to 90 hours has been reported when ethanol is coingested because ethanol competitively inhibits methanol metabolism by alcohol dehydrogenase (5).

Methanol itself has few direct effects. Mild ethanol-like CNS depression has been reported (3). Methanol is about half as potent as ethanol in this regard. Nausea, vomiting, and abdominal pain may develop shortly after ingestion of a concentrated methanol solution. During the early stages of poisoning, the diagnosis is confirmed by measuring the serum methanol level, but this laboratory process is usually not readily available or the results are not rapidly obtainable. Because of methanol's low molecular weight (32 g/mol), high serum concentrations can increase the serum osmolality. Therefore, the diagnosis can be suggested by an increased osmolal gap, that is, the difference between the measured osmolality and the calculated osmolality (2 × sodium [mEq/L] + blood urea nitrogen [mg/dL]/2.8 + glucose [mg/dL]/18 + ethanol [mg/dL]/4.25) (6). The "normal" range for the osmolal gap has been debated extensively and has been reported to vary from −10 to 20 mOsm (7). Although an osmolal gap above 20 indicates exogenous osmoles of some kind, an osmolal gap within the normal range does not exclude the possibility of a toxic methanol ingestion. The serum methanol level can be estimated (in mg/dL) by multiplying the excess osmolal gap by 2.6, the amount of methanol that increases the osmolality by 1 mOsm/kg H_2O. Because the molecular weight of methanol is lower than for ethylene glycol, the same volume causes a greater osmolal gap and is easier to detect. Shortly after ingestion, when the highest methanol levels and osmolal gap are present, metabolic acidosis can be absent because significant conversion to formate has not yet occurred. Severity of illness is best predicted by the degree of anion gap, osmolal gap, and acidosis. Patients with anion gaps less than 30, osmolal gaps below 49, and pH values greater than 7.22 usually survive (8).

Clinical features during the intermediate stage of poisoning include anorexia, headache, nausea, and vomiting, accompanied or followed by increasing hyperventilation as a result of progressive anion gap metabolic acidosis (3). The normal anion gap ([Na] − [Cl + HCO_3]) is 12 ± 2 mEq/L. Visual symptoms (blurred vision, decreased acuity, halo vision, tunnel vision, photophobia, and "snowfields") might precede or accompany the aforementioned symptoms. Objective

signs, such as dilated pupils that are partially reactive or nonreactive to light and funduscopic findings of optic disk hyperemia with blurring of the margins, occur later. During this intermediate stage, the diagnosis is confirmed by detecting methanol or formate in the serum; an elevated osmolal gap might or might not be present. Occasionally, patients present with abdominal pain from associated acute pancreatitis (3).

Without treatment, late effects of coma and respiratory and circulatory failure can ensue. In a few patients, methemoglobinemia develops from an interaction between formate and the ferric part of hemoglobin. In the late stages of methanol poisoning, when most or all of the methanol has been metabolized to formate, the anion gap is elevated, methanol might not be detectable so the osmolal gap is normal. In this situation, measurement of the serum formate concentration could be the only way to confirm the diagnosis. Toxic effects on the basal ganglia do not immediately produce detectable signs and symptoms, because they are masked by pronounced CNS depression. Survivors might later experience parkinsonism and polyneuropathy, with basal ganglion necrosis noted on computed tomography (CT) scan or magnetic resonance imaging (MRI) (9).

DIFFERENTIAL DIAGNOSIS

Other causes of metabolic acidosis and increased serum osmolality should be considered in the differential diagnosis (Fig. 300.2), particularly when the history is unclear and quantitative methanol and formate levels are not readily available. Increased anion and osmolal gaps also occur in ethylene glycol poisoning. Differentiating the two may be difficult, but the treatments are essentially the same. Visual complaints suggest methanol poisoning, whereas hypocalcemia, seizures, and urine oxalate crystals suggest ethylene glycol poisoning (3).

Anion gap	Osmolal gap	Both
Ketoacids	Diabetes	Ethylene glycol
Lactate	Ethanol	Methanol
Paraldehyde	Mannitol	
Salicylate	Other alcohols	
Uremia		

FIGURE 300.2 Causes of an increased anion and osmolal gaps.

ED EVALUATION

Important aspects of the history include the amount, concentration, if the original product was diluted, and time of methanol ingestion; the nature and onset of symptoms; and whether ethanol was coingested. The intent of the ingestion—accidental versus intentional—should be ascertained, since intentional ingestions are often more serious. Usually, accidental ingestions are of only a small amount and much less likely to be toxic than intentional ingestions. Patients should be questioned carefully about the presence or absence of visual complaints, gastrointestinal (GI) symptoms, and a feeling of intoxication. The physical examination should focus on vital signs (especially respiratory rate) and the patient's neurologic, visual, and cardiopulmonary status. Visual acuity and funduscopic findings should be documented.

The laboratory evaluation of early-presenting patients should include methanol level, and if not readily available, osmolality, ethanol, electrolytes, blood urea nitrogen, creatinine, glucose to calculate an osmolal gap. Quantitative serum methanol and/or formic acid levels should be determined by gas chromatography and mass spectrometry (GC/MS). If the diagnosis is based on the osmolal and anion gaps, osmometry must be performed by the freezing point depression technique, not by the vapor pressure technique, because

the latter does not detect the increased osmolality caused by volatile alcohols.

Blood gas analysis with serum lactate can detect the metabolic acidosis and should be repeated to assess the degree of acidosis if treatment is delayed. A chest radiograph and an electrocardiogram can be obtained if clinical toxicity is pronounced. A CT scan or MRI of the brain should be performed on patients with coma or persistent neurologic dysfunction.

KEY TESTING

The laboratory evaluation should include the following:

- Quantitative serum methanol and/or formic acid levels by GC/MS for all patients
- If methanol levels are delayed or if patients present late, add blood gas analysis, electrolytes, blood urea nitrogen, creatinine, glucose
- A chest radiograph and an electrocardiogram if clinical toxicity is pronounced

ED MANAGEMENT

General treatment measures include supportive care and GI decontamination. Immediate gastric aspiration via nasogastric tube may be helpful for intentional ingestions if performed within 1 hour after ingestion. Activated charcoal is probably of limited value because of limited binding (3).

Specific treatment of methanol poisoning includes intravenous (IV) sodium bicarbonate for metabolic acidosis, antidotal therapy with ethanol or fomepizole to inhibit methanol metabolism to formate, and hemodialysis to remove methanol and formate. Folinic acid (leucovorin), 1 mg/kg IV up to 50 mg every 4 hours, may be of value to increase the metabolism of formate (10). If folinic acid is unavailable, folic acid in the same dose can be used.

Metabolic acidosis should be treated aggressively with enough sodium bicarbonate ($NaHCO_3$) to fully correct acidemia:

$$NaHCO_3 \text{ dose} = 0.7 \times kg \times (24 - \text{actual } [HCO_3^-]),$$

where 0.7 is the volume of distribution of bicarbonate, 24 is the desired $[HCO_3^-]$, and kg represents the lean body weight.

$NaHCO_3$ should be given in 1 mEq/kg increments. As much as 400 to 600 mEq of $NaHCO_3$ could be required during the first few hours. Bicarbonate therapy decreases the amount of undissociated formic acid and CNS toxicity (3). Hence, metabolic acidosis from methanol poisoning should *always* be treated with bicarbonate. Frequent reassessment of acid–base and electrolyte status is prudent during treatment.

Alkali treatment must be accompanied by administration of ethanol or fomepizole to block further production of formic acid. If methanol poisoning is suspected and a level cannot readily be obtained, fomepizole or ethanol therapy should be started in any patient with an increased osmolal gap, acidosis, symptoms, or a potentially toxic ingestion suggested by the history. Antidotal treatment can be discontinued when the methanol level drops below 20 mg/dL, provided the acid–base status is normal and the patient is experiencing no complications.

Fomepizole (4-methylpyrazole; Antizol) is a safe alternative to ethanol (5,10). The loading dose of 15 mg/kg IV is followed by doses of 10 mg/kg IV every 12 hours. During hemodialysis, the dosing frequency should be increased to every 4 hours. Fomepizole is superior to ethanol as an antidote, because it does not carry the risk of respiratory depression, the need to monitor blood ethanol levels, or the requirement for an ICU setting for IV infusion; the only negative consideration is its cost.

Ethanol antidotal treatment, at a therapeutic blood ethanol level of at least 100 mg/dL is still effective. However, the ethanol level necessary to block methanol metabolism varies with the blood level of methanol because of competition for alcohol dehydrogenase. The molar ethanol concentration should be at least one-fourth of the molar methanol concentration (3).

An approximate blood ethanol level of 100 mg/dL can be achieved by giving a bolus dose of 0.6 mg/kg, followed by 66 to 154

mg/kg/hr intravenously or orally (the higher maintenance dose is for heavy drinkers). Mixing 50 mL of absolute ethanol with 500-mL isotonic glucose yields a 10% ethanol solution. With this solution, a bolus of 10 mL/kg (>0.5 hour), followed by 1.5 mL/kg/hr can be the initial dose. The maintenance infusion should be adjusted according to frequently measured ethanol levels. As a rule of thumb, the maintenance dose of ethanol should be doubled during hemodialysis. If this is not done, methanol metabolism can resume as ethanol is removed, thus allowing toxicity despite hemodialysis.

Hemodialysis efficiently removes methanol and formate and helps to correct the metabolic acidosis (3,5). The one absolute indication for hemodialysis is any visual impairment in a patient with metabolic acidosis or a detectable methanol level. Other indications include severe acidemia (particularly if the patient is unresponsive to bicarbonate and ethanol therapy), a blood methanol level above 50 mg/dL (because of the very slow elimination of methanol during antidotal therapy), renal insufficiency, or ingestion of more than 1 g/kg of methanol. With the use of fomepizole, most patients need dialysis only to shorten the duration of fomepizole treatment by removing unmetabolized methanol. However, in severe poisoned patients with pronounced acidemia and visual disturbances, hemodialysis should be performed to remove formate and methanol. Hemodialysis should be continued until the blood methanol level is below 20 mg/dL and acidemia is corrected. If methanol analyses are unavailable, hemodialysis should be continued for at least 8 hours or until the osmolal gap is normal (5,7). Peritoneal dialysis is not effective enough to be clinically useful.

CRITICAL INTERVENTIONS

- Administer ethanol or fomepizole to patients with signs, symptoms, or laboratory evidence of methanol poisoning
- Administer IV sodium bicarbonate to patients with acidemia
- Arrange hemodialysis for patients with methanol poisoning that is severe or refractory to other treatment

DISPOSITION

When the diagnosis of methanol poisoning is made or suspected, a nephrologist should be consulted, because many of these patients require hemodialysis, especially when admitted in a late stage. If hemodialysis is likely to be needed, the patient should be transferred to a facility with this capability. Bicarbonate and antidotal therapy should be given prior to and during transport.

If a methanol level is not immediately available, asymptomatic patients with known or suspected methanol ingestion and a normal anion and osmolal gap should be observed and reevaluated for clinical and acid–base status until the methanol level becomes known. Patients with signs, symptoms, or laboratory evidence of methanol intoxication should be admitted, usually to an ICU because of the frequency of monitoring required. They should also have an ophthalmologic evaluation for detection and management of ocular injury.

Common Pitfalls

- Failure to consider methanol poisoning in the differential diagnosis of metabolic acidosis of unknown origin
- Failure to consider the possibility of multiple victims when the source of methanol is unknown or is known to be contaminated ethanol
- Failure to appreciate that the absence of early symptoms, a normal anion gap, or a normal osmolal gap does not exclude a potentially serious methanol intoxication
- Failure to assess and document visual acuity
- Failure to observe and monitor patients with known or suspected methanol ingestion until a methanol level can be obtained or until the time of expected toxicity has passed without incident
- Failure to fully correct acidemia
- Failure to appreciate that ethanol and fomepizole are removed by hemodialysis and to adjust their dosing during this procedure accordingly

- Failure to have the visual function of methanol-poisoned patients assessed formally by an ophthalmologist

CHAPTER 301

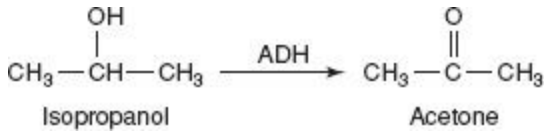
Isopropanol, Acetone, and Other Glycols

Jeffrey R. Suchard

Although ethylene glycol (Chapter 299) and methanol (Chapter 300) are potentially more dangerous, exposures to isopropanol and acetone occur more frequently and are more likely to be encountered in the emergency department (ED).

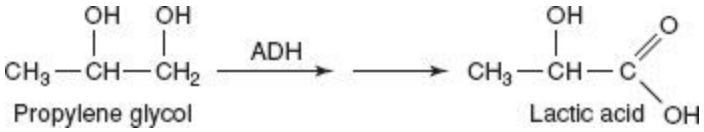
Isopropanol (2-propanol, isopropyl alcohol) is a disinfectant, solvent, cleaner, and deicing agent. Rubbing alcohol is the most common household source, typically containing 70% isopropanol by volume. Despite a slightly bitter taste and distinctive, pungent smell, isopropanol is the most commonly ingested nonbeverage alcohol. Other routes of exposure include inhalation and transdermal absorption, particularly among small children. Isopropanol is rapidly absorbed from the stomach; peak serum levels can be measured within 30 minutes (1,2). Clinical effects are evident within 0.5 to 1.5 hours (3). Isopropanol is a central nervous system (CNS) depressant about twice as potent as ethanol.

Isopropanol is primarily metabolized by alcohol dehydrogenase (ADH) to acetone (eFig. 301.1). Ketonemia and ketonuria caused by the presence of acetone occur rapidly after exposure to isopropanol (1). Unlike methanol and ethylene glycol, no organic acid metabolites are produced, and an elevated anion-gap metabolic acidosis is not expected. The serum half-life of isopropanol varies considerably, but is in the range of 2.5 to 6 hours.



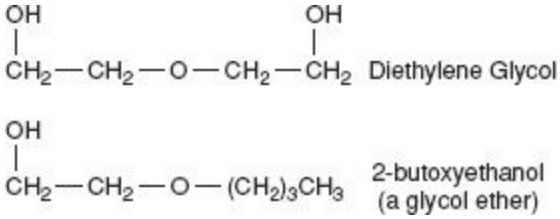
eFIGURE 301.1 Isopropanol metabolized to acetone.

Acetone (2-propanone, dimethyl ketone), a metabolite of isopropanol (4), is a solvent in industry and the home. Fingernail polish remover is a common cause of acetone exposures (5). Acetone is rapidly absorbed and then excreted unchanged (4). Reports of acetone's elimination half-life vary widely but range from 17 to 31 hours (4,5). Propylene glycol (1,2-propanediol [PG]) is a solvent and CNS depressant found in many foods, cosmetics, and intravenous medications. Roughly 50% of PG is excreted unchanged into the urine, and the remainder is metabolized via ADH and aldehyde dehydrogenase into lactic acid (eFig. 301.2).



eFIGURE 301.2 Propylene glycol metabolized to lactic acid.

Diethylene glycol (DG), another common solvent and CNS depressant, consists of two ethylene glycol molecules connected by an ether bond (eFig. 301.3). The strong ether bond is not metabolized in humans to release free ethylene glycol, but DG poisoning can still produce renal failure and neurologic toxicity. Epidemics of renal failure have occurred when DG has been used as an inappropriate substitute for glycerin in oral liquid medications (6).



eFIGURE 301.3 Other glycols.

Glycol ethers are compounds that consist of a glycol, usually ethylene glycol, connected to an alkyl group by an ether bond. Ethylene glycol-butyl-ether (2-butoxyethanol), a typical glycol ether, is shown in eFigure 301.3. Glycol ethers are used as industrial solvents, as glass and surface cleaners, and in automobile brake fluid.

CLINICAL PRESENTATION

Isopropanol poisoning is characterized by CNS depression, gastrointestinal effects, ketosis, and an elevated osmolal gap (OG) without metabolic acidosis. Two common scenarios are (a) chronic alcoholics seeking an alternative when deprived of ethanol; and (b) exploratory ingestions by children. It is difficult to correlate the degree of intoxication with serum isopropanol levels, probably because of cross-tolerance to isopropanol in alcoholics or lack of previous exposure to intoxicants among children. Complicating the issue is the ubiquitous presence of acetone, an isopropanol metabolite that is also a CNS intoxicant.

With a few exceptions, signs and symptoms of isopropanol and acetone intoxication are very similar to those of ethanol. The disinhibited phase that may be seen with early ethanol intoxication has not been reported with isopropanol, but the CNS depressant effects are otherwise the same. Patients ingesting isopropanol often have higher levels of acetone than isopropanol by the time of presentation. Because of its slower metabolism and the intoxicating effect of its acetone metabolite, the duration of isopropanol intoxication is longer than ethanol. Gastrointestinal effects are more common than with ethanol and include nausea, vomiting, abdominal pain, and hemorrhagic gastritis.

Acetone produces a characteristic fruity or ether-like odor in the breath. Serum acetone levels after isopropanol or acetone ingestion often greatly exceed those found in diabetic ketoacidosis, so this olfactory clue may be even more obvious than usual. Ketonemia and ketonuria occur rapidly after isopropanol or acetone poisoning (1).

Most cases of PG toxicity occur iatrogenically in hospitalized patients, particularly with high doses of intravenous benzodiazepines (7,8), but it can also result from ingestion of PG-containing household products such as cosmetics and automotive antifreezes (sold as safer alternatives to ethylene glycol). Signs and symptoms include CNS depression, hyperosmolality, lactic acidosis, and renal insufficiency.

DG and glycol ether poisoning may result in CNS depression, metabolic acidosis, renal failure, hepatitis, and pancreatitis. Glycol ethers can also cause hemolysis, hypotension, hypoglycemia, hematuria, and acute respiratory distress syndrome (9).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of isopropanol and acetone exposure includes any of the other CNS depressants, and other medical or surgical conditions that alter mental status, including intracranial trauma, CNS infection or tumors, hypoglycemia, and other severe metabolic derangements.

The primary exogenous substances in the differential diagnosis are other alcohols. Patients ingesting any of the short-chain alcohols typically present with a similar clinical picture of CNS depression and an elevated OG. Differentiating the early stages of intoxication with any of these agents may be difficult. Fortunately, the most commonly ingested alcohol is ethanol, which can be rapidly quantified by most clinical laboratories. Late-presenting patients might be differentiated by an anion-gap metabolic acidosis (methanol and ethylene glycol), renal insufficiency (ethylene glycol), visual symptoms (methanol), hyperlactatemia (PG), and the smell of acetone on the breath (isopropyl alcohol or acetone). Patients with ethanol-like CNS effects, an elevated OG, and a normal anion gap and who smell like acetone may presumptively be diagnosed with isopropanol or acetone toxicity pending laboratory confirmation. Concurrent ingestion of isopropanol and ethanol or another “toxic alcohol” is not uncommon (2).

Ketones from isopropanol or acetone ingestion may falsely elevate measurement of serum creatinine (10), and an elevated creatinine with a normal blood urea nitrogen (BUN) suggests this diagnosis. Renal insufficiency from ethylene glycol should occur in conjunction with an increased BUN and a significant anion-gap metabolic acidosis. Other causes of ketosis to consider include diabetic ketoacidosis and alcoholic ketoacidosis, both of which also elevate the OG, and starvation ketosis. Elevated serum acetone levels are found in patients with ketoacidosis, although these levels are usually lower than those seen with isopropanol or acetone ingestion.

Although fingernail-care product ingestion is a common and usually benign source of acetone exposure, care should be taken to confirm the history and product ingredients in such cases. The ingestion of artificial nail remover (as opposed to nail polish remover) containing acetonitrile, rather than acetone, has caused fatal cyanide toxicity.

PG-induced lactic acidosis, especially among hospitalized patients receiving IV medications with PG as a solvent, may be confused with many other serious causes of lactic acidosis, including hypoxia, hypotension, and sepsis that need to be excluded before ascribing the lactic acidosis to PG toxicity.

ED EVALUATION

The history should include identification of the substance(s) involved, concentration, route(s) of exposure, estimated volume ingested, and time elapsed since exposure. Any history of potential co-ingestants or trauma should be elicited. Early definitive product identification can help identify potential disasters, such as acetonitrile-containing nail-care products in children or methanol and ethylene glycol ingestion by chronic alcoholics deprived of ethanol. Physical examination should focus on the patient's mental status, airway, and vital signs.

Patients presenting with altered mental status should have a rapid glucose determination to rule out hypoglycemia. With serious intoxication, laboratory tests should include a quantitative level of

the substance involved (if available). Routine serum chemistries (to rule out anion-gap metabolic acidosis), an ethanol level, arterial blood gas, and measurement of serum and urinary ketones may also be helpful where the diagnosis is not clear by history. The close chemical structural relationship between ethanol, isopropanol, and acetone can cause analytical interference when employing breathalyzer ethanol tests and enzymatic ethanol assays using ADH.

The serum OG can be helpful as a screening tool for detecting exogenous low–molecular-weight alcohols or glycols. A serum osmolality measured by freezing-point depression exceeding the calculated osmolality (2[Na] + [BUN]/2.8 + [Glucose]/18 + [Ethanol]/4.2) suggests the presence of isopropanol, acetone, methanol, ethylene glycol, or PG. If the identity of the substance is known, its serum concentration in milligrams per deciliter can be roughly estimated by multiplying the OG by the substance's molecular weight and dividing by 10. The molecular weight of isopropanol is 60 g/mol, acetone is 58 g/mol, and PG is 76 g/mol. For example, if a patient with an acetone ingestion has an OG of 20, the estimated serum acetone concentration is (20 × 58)/10 = 116 mg/dL. Because the molecular weights of glycol ethers are higher than those of the other alcohols, toxic levels of glycol ethers often do not significantly elevate the OG.

KEY TESTING

- Chemistry panel, to calculate serum anion gap
- Serum osmolality and ethanol levels should be ordered along with the chemistry panel to calculate the serum OG
- Serum levels of isopropanol and acetone, if available in a clinically relevant timeframe

ED MANAGEMENT

Treatment of isopropanol or acetone toxicity is supportive, with most patients requiring only observation. Early-presenting patients should be observed for deterioration, as toxicity should manifest within the first few hours. Activated charcoal does not bind these

toxins well, and is not recommended unless the patient also recently ingested toxins that will adsorb to it. Patients not adequately protecting their airway should be intubated. Hypotension, if present, should be treated with intravenous saline and, if necessary, vasopressor agents.

Hemodialysis can greatly enhance isopropanol and acetone elimination. Hypotension refractory to treatment with intravenous saline is the primary indication for hemodialysis. Because acetone is not substantially more toxic than isopropanol, ethanol or fomepizole treatment to inhibit alcohol dehydrogenase is not useful. Patients with abdominal pain or heme-positive emesis may have a hemorrhagic gastritis and should be evaluated for gastrointestinal bleeding and anemia.

The treatment of severe toxicity such as renal failure and acidosis from DG, PG, or glycol ethers should include ethanol or fomepizole and hemodialysis, with similar doses and protocols as used with ethylene glycol (Chapter 299) or methanol (Chapter 300) toxicity (7,9).

CRITICAL INTERVENTIONS

- Support the airway and respiratory function in patients with CNS depression.
- Administer intravenous fluids and vasopressors for hypotension.
- Consider hemodialysis for profound CNS depression, refractory hypotension, metabolic acidosis, or renal failure.
- Administer ethanol or fomepizole to patients with severe DG, PG, and glycol ether poisoning.

DISPOSITION

Patients with minor exposures to isopropanol or acetone, such as pediatric non-intentional ingestions, will need only 2 or 3 hours of observation to ensure they do not develop CNS depression. Patients with mild symptoms can be observed as with ethanol intoxication. Patients with coma, hypotension, metabolic disturbances, or end-

organ toxicity should be admitted to an intensive care unit with poison center, toxicologist, and nephrologist consultation as needed.

Common Pitfalls

- Assuming that all isopropanol and acetone exposures are benign.
- Failure to monitor and re-evaluate both asymptomatic and intoxicated patients.
- Failure to appreciate that acetone and isopropanol affect breathalyzer measurement.
- Failure to appreciate that acetone causes falsely elevated serum creatinine levels and diagnosing renal failure when the BUN is normal.
- Failure to appreciate that DG, PG, and glycol ethers can cause toxicity similar to ethylene glycol.

PART 3 • ANALGESICS

CHAPTER 302 Acetaminophen

Jeffrey Brent

Acetaminophen (N-acetyl-*p*-aminophenol, or APAP) is the most commonly used analgesic/antipyretic in the world. Given its widespread availability, poisoning with acetaminophen is common. Because many lay people underestimate its toxicity, suicide gestures may result in unintentional actual suicides. In 2012, nearly 150,000 potential APAP poisonings and almost 140 deaths as a result of acetaminophen alone and in combination with other agents were reported to US poison centers (1). In 2011, medical toxicologists personally treated over 900 cases of APAP toxicity (2). These figures represent only a fraction of the total number of incidents.

Acetaminophen itself has very little intrinsic toxicity. It is almost entirely metabolized in the liver by the pathways shown in Figure 302.1. About 94% of an ingested therapeutic dose of APAP is metabolized to the nontoxic glucuronide (52%) or sulfate (42%) conjugates, which are excreted in the urine. Of the remaining 6% of the dose, about half is excreted unchanged in the urine, and a similar amount undergoes oxidative metabolism primarily by the 2E1 isozyme of the hepatic P450 system (CYP2E1) to form a highly reactive intermediate, N-acetyl-*p*-benzoquinoneimine (NAPQI) (3). With therapeutic APAP dosing, the small amount of NAPQI produced is rapidly conjugated by glutathione and excreted as the mercapturate conjugate plus other minor metabolites, all of which are nontoxic.

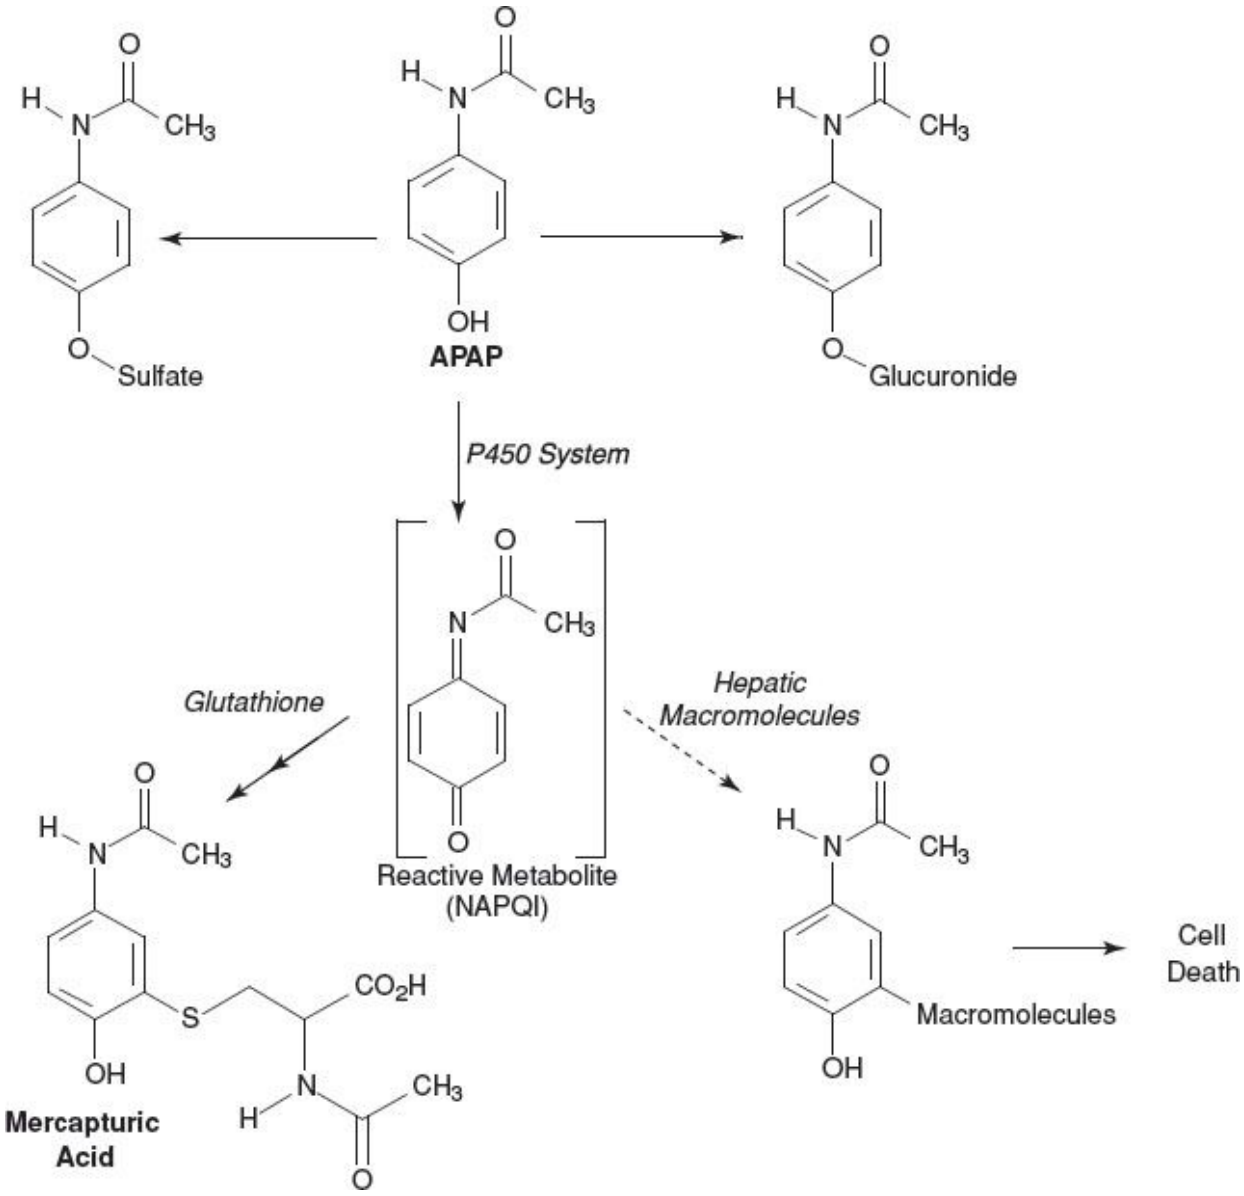

FIGURE 302.1 Metabolic pathways for acetaminophen metabolism.

In animal models, toxicity occurs when hepatic glutathione stores are depleted by about 70%, which renders the hepatocytes vulnerable to the effects of NAPQI (3). In the setting of inadequate glutathione stores, NAPQI is conjugated by hepatic macromolecules, which is generally thought to be the cause of hepatocyte death in APAP poisoning. Histologically, necrosis occurs at the highest concentrations of CYP2E1 in the centrilobular (zone III; perivenular) portions of the hepatic lobule (3).

Although the clinical picture of APAP overdose is predominantly one of hepatotoxicity, some patients also have nephrotoxicity. Rarely, and only anecdotally, renal damage has been reported to occur in the absence of substantial hepatotoxicity. The nephrotoxicity is most likely a result of renal APAP biotransformation to the toxic NAPQI metabolite by CYP2E1 in the kidney. Additionally, renal failure is an occasional concomitant complication of severe APAP-induced hepatotoxicity as a result of the hepatorenal syndrome.

CLINICAL PRESENTATION

Acetaminophen toxicity can be divided into four stages (Table 302.1). The first stage of APAP poisoning is a relatively subtle period characterized by nausea, vomiting, and general malaise. In this phase, APAP is being absorbed and metabolized, and glutathione stores are being consumed. Although hepatotoxicity is beginning, it is often not apparent clinically or in routine laboratory results. Phase I typically lasts <24 hours. The antidote N-acetylcysteine (NAC) is most effective during this early phase and is virtually 100% effective in preventing hepatotoxicity if initiated within 8 hours of ingestion.

TABLE 302.1
Stages in the Clinical Course of Acetaminophen Toxicity

Stage	Time after Ingestion	Characteristics
I	0.5–24 hrs	Anorexia, nausea, vomiting, malaise, pallor
II	24–48 hrs	Right upper quadrant abdominal pain and tenderness; elevated bilirubin, prothrombin time, hepatic enzymes; oliguria
III	72–96 hrs	Peak liver-function abnormalities; anorexia, nausea, vomiting, malaise may reappear
IV	4 d–2 wks	Resolution of hepatic dysfunction or fulminant hepatic failure

Modified from Linden CH, Rumack BH. Acetaminophen overdose. *Emerg Med Clin North Am.* 1984;2:103.

During the second phase, which usually starts late on the day of the ingestion, the gastrointestinal effects of phase I resolve, and plasma concentrations of APAP are low or nondetectable. (Serum and plasma APAP concentrations can be considered to be equivalent.) The hepatotoxic effect of the NAPQI, which has not been inactivated by glutathione, begins to cause hepatocellular destruction. The predominant clinical picture is of hepatotoxicity but, as toxicity evolves, some cholestatic features may occur. However, primary or prominent cholestatic injury is not caused by APAP.

Phase III of acetaminophen toxicity is the time of maximum hepatotoxicity. During this phase, transaminases will peak and then decline, but effects on coagulation may continue to increase. Patients who present in stage II or III may have right upper quadrant pain, nausea, vomiting, jaundice, bleeding, and encephalopathy. Associated with this is a progressive increase in bilirubin, alanine aminotransferase (ALT), aspartate aminotransferase (AST) levels, and PT/INR. The magnitude of these liver-function abnormalities can be dramatic, with ALT and AST levels of 10,000 to 20,000 IU/L frequent. In most cases, these abnormalities peak in 48 to 96 hours (stage III) and gradually resolve.

In the final phase (IV), there will be either recovery or fulminant hepatic failure (FHF). Patients with severe untreated APAP toxicity exhibit a pattern of continued rising prothrombin time, bilirubin, and ammonia levels as the AST and ALT decline. This pattern signifies FHF. However, most patients, even those with severe hepatotoxicity, eventually recover, with normal livers. Patients who recover from APAP hepatotoxicity should not have residual liver abnormalities, and there is no reason for concern regarding future therapeutic APAP use.

A number of poisoning cases have a high anion-gap metabolic acidosis, thought to be a poor prognostic sign of liver failure. In addition, some cases may also be related to elevated levels of 5-oxoproline, also known as pyroglutamic acid, which is involved in glutathione metabolism. Most of these patients are women with chronic acetaminophen exposure, significant malnutrition, and other

chronic disease, most recover with supportive treatment. The significance of this entity remains unclear.

The relationship between the plasma concentration of APAP, the time after acute ingestion, and the potential for toxicity is described by the nomogram developed by Rumack and Matthew (Fig. 302.2) (3). The nomogram stratifies patients into risk categories of "probable" or "possible" hepatotoxicity. Toxicity is not generally expected in the "possible risk" area, which includes a 25% margin of safety to account for possible errors in establishing the time of ingestion. Possible risk is traditionally considered an indication for antidotal therapy in the United States, although some medical toxicologists and poison centers use the "probable toxicity" line starting at 200 μg/mL at 4 hours. There is considerable variation worldwide in the treatment thresholds used. Some countries use the "probable toxicity" line starting at 200 μg/mL at 4 hours. The UK has recently adopted the line starting at 100 μg/mL at 4 hours, although the empirical justification for using such a low threshold is weak. Denmark has abandoned the nomogram and simply treats all patients who give a history of APAP ingestion above therapeutic amounts. Use of low, or nonexistent, thresholds may subject patients to unnecessary hospitalizations and possible iatrogenic complications, more than doing any good.

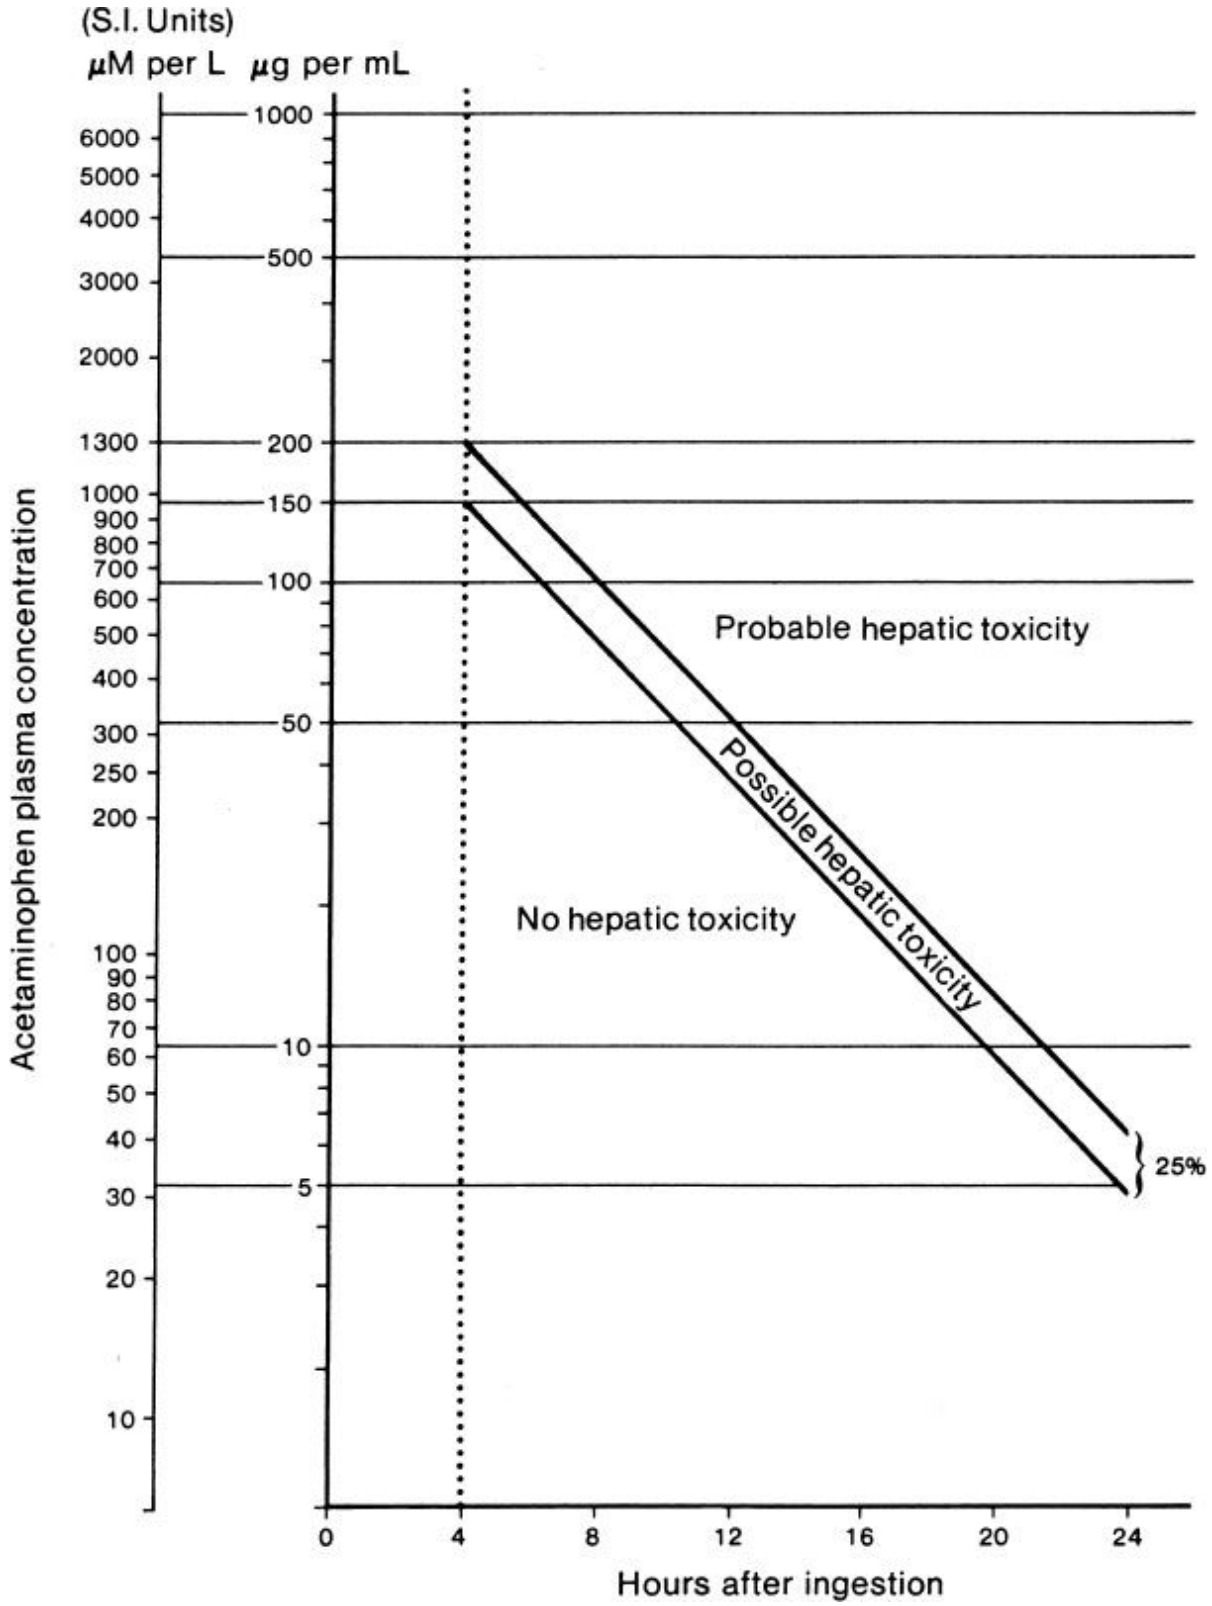

FIGURE 302.2 Rumack–Matthew nomogram for acetaminophen poisoning. Relation between plasma APAP levels and toxicity

correlated with time after exposure. (Reproduced with permission from Rumack BH. Acetaminophen overdose in children and adolescents. *Pediatr Clin North Am. 1986;33:691–701.)*

The nomogram begins at 4 hours after ingestion and extends to 24 hours. Early plasma APAP concentrations obtained before this time—during the absorption and distribution phases—are difficult to interpret, however, early APAP concentrations of <100 μg/mL suggest a lack of toxicity risk. Both nomogram lines have a slope equivalent to a 4-hour half-life, so by remembering that they begin at plasma concentrations of 150 and 200 μg/mL, the level at each subsequent 4-hour time can be calculated by halving the previous level.

The APAP nomogram is based only on initial plasma concentrations. Repeat levels offer no further useful information, can cause confusion and their utility has not been validated. Although this has been recommended for sustained-release APAP overdose, the value of this practice for determining risk of hepatotoxicity has not been validated. Based on the known volume of distribution of APAP of 0.9 to 1.0 L/kg, an ingestion of 10.5 g APAP in a 70-kg adult, or 150 mg/kg in a child, may produce plasma concentrations in the possible toxicity range.

The current nomogram is derived solely from adult cases. Children with toxic plasma levels after an acute overdose appear to be less susceptible to APAP toxicity than adults (4). Patients who have ingested a potentially toxic dose of APAP and have a history of anorexia or severe malnutrition may be more susceptible to APAP hepatotoxicity because of decreased glutathione stores. Patients with chronic liver disease tend to have glutathione stores maintained even as their content of CYP2E1 fall, hence they do not appear to be at a significant risk of toxicity with therapeutic dosing. Patients with a history of alcohol abuse also do not appear to be at an increased risk of toxicity at therapeutic doses unless they are severely malnourished in acute overdose. These patients can be evaluated using the standard nomogram.

DIFFERENTIAL DIAGNOSIS

In the earliest stage of APAP poisoning, the presumptive diagnosis is made by a history suggestive of overdose. Because there are no consistently reliable or pathognomonic signs or symptoms, the possibility of occult APAP poisoning must be considered when one is confronted with any overdose. The common practice of measuring APAP levels with every intentional ingestion increases the detection of any APAP in the plasma which must alert the clinician to the possibility of a toxic APAP ingestion, especially in the setting of elevated transaminases.

The patient in stage II, III, or IV of APAP toxicity presents a different diagnostic challenge. By this time, there may be little or no detectable APAP in the plasma, so the diagnosis depends heavily on the history and clinical suspicion.

The differential diagnosis of hepatic injury includes most commonly viral, autoimmune, ischemic, cholestatic or chemical etiologies. Virtually any drug can cause hepatotoxicity as an idiosyncratic reaction. The chemistry profiles typically seen with the different types of hepatitis are shown in Table 302.2. As shown in Figure 302.3, liver function test (LFT) results may not rise dramatically until a day after the ingestion, although LFT, PT/INR elevations are often seen within the first day (5).

TABLE 302.2
Laboratory Values in the Common Acute Hepatitides: Viral, Alcoholic, Acetaminophen

Hepatotoxin	Acute Viral Studies	AST (IU/L)	ALT (IU/L)
Viral	Usually positive	Hundreds to low thousands	Variable but less than AST
Alcohol	Negative	Usually <300 or 10× normal	Usually ALT/AST >2
APAP	Negative	May be very high	Much less than AST

AST, aspartate aminotransferase; ALT, alanine aminotransferase.

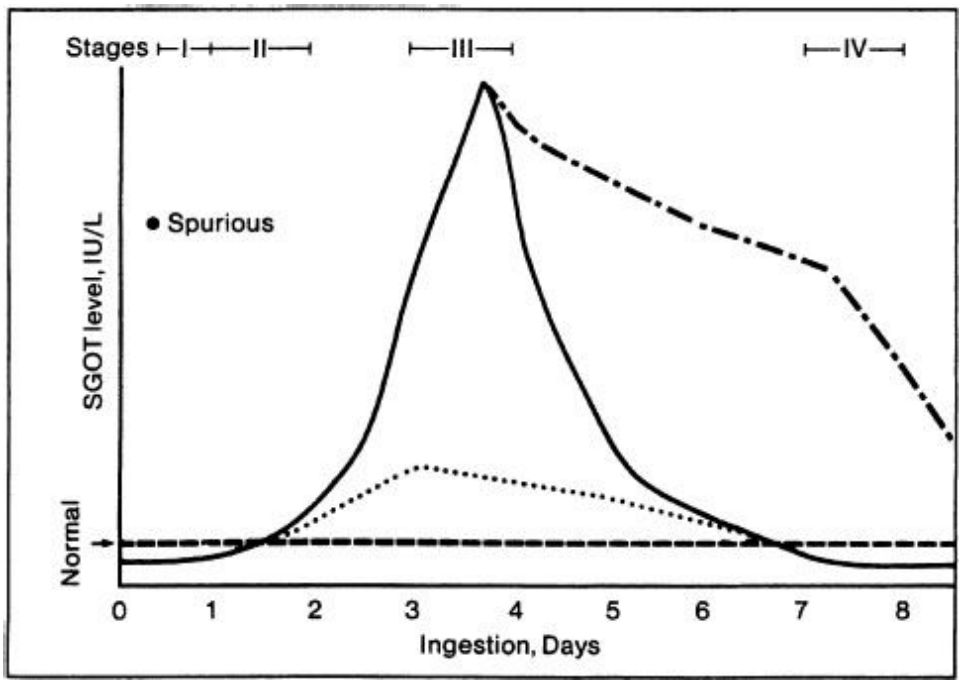

FIGURE 302.3 *Dotted line:* the course of those who received acetylcysteine. *Solid line:* those with natural a course. *Dotted-dashed line:* those with a severe course. (Reproduced with permission from Smilkstein MJ, Knapp GL, Kulig KW, et al. Efficacy of oral N-acetylcysteine in the treatment of acetaminophen overdose. Analysis of the national multicenter study [1976 to 1985]. *N Engl J Med.* 1988;319:1557–1562.)

ED EVALUATION

The amount, formulation, and time(s) of APAP or other drug ingestion should be noted. Because of the many over-the-counter medications and prescription opioid combinations containing APAP, the patient may not even be aware of the amount ingested. The history should address risk factors such as anything affecting nutritional status (which might reduce hepatic GSH concentrations) such as chronic severe malnutrition or acute starvation, and the use, or misuse of opioid–APAP combinations. The physical examination should focus on the vital signs and assessment of cardiovascular, gastrointestinal, and neurologic function and hydration status. A plasma APAP concentration should be obtained and, for acute ingestions, compared to the nomogram. If the level is potentially

toxic, or the time of ingestion is unknown and APAP is present, baseline LFTs (AST, ALT, and total bilirubin levels and prothrombin time) and plasma creatinine concentration should be obtained. A normal presenting plasma ALT level has been shown to have an approximately 100% negative predictive value for significant liver injury in treated patients (6).

The Rumack–Mathew nomogram is based on single ingestions and cannot be applied to cases with a history of excessive APAP ingestion over more than a single point in time. Based on empiric observation, these patients can be evaluated for possible APAP-induced toxicity or risk of such toxicity if:

1. They are under 6 years of age and they have ingested either (a) 100 mg/kg or greater over a single 24-hour period or (b) 150 mg/kg or greater per 24-hour period for the preceding 48 hours or (c) 100 mg/kg or greater per 24-hour period for the preceding 72 hours.
2. Patients 6 years old or older and they have ingested either (a) at least 10 g or 200 mg/kg (whichever is less) over a single 24-hour period or (b) 6 g or 100 mg/kg (whichever is less) per day for the preceding 2 days.
3. Patients who are malnourished, fasting, or taking an agent known to induce CYP450 2E1 (e.g., isoniazid), who have ingested more than 4 g or 100 mg/kg (whichever is less) (7).

Patients presenting with a history of ingesting excess amounts of APAP over a period of time that meet the criteria outlined above should be treated with NAC if their plasma APAP concentration is $\leq$20 μg/mL or if there hepatic transaminases are elevated (unless these are known to be chronic). Treatment should be continued until the plasma APAP level is $<$15 μg/mL and transaminases are clearly falling.

Urinary organic acid screening may detect 5-oxopropline in patients with an unexpected high anion-gap metabolic acidosis. Future testing may rely on biomarkers: (1) microRNA-122 (which has high hepatic specificity), (2) high mobility group box-1 (a marker of apoptosis), and (3) keratin 18 (a marker of necrosis, or if measured as the caspase-cleaved molecule, it is a marker of

apoptosis) which have been shown to be highly sensitive for the prediction of hepatic injury and are elevated before transaminases rise (8).

KEY TESTING

- A plasma APAP concentration should be obtained on all overdoses, regardless of the patient's history of taking, or not taking, APAP
- LFTs and a plasma APAP concentration in patients who have been taking excessive therapeutic doses

ED MANAGEMENT

Advanced life-support measures should be provided if necessary (e.g., for coingested agents). Intravenous fluids may be required for patients with vomiting and dehydration. Treatment of acute APAP overdose is directed toward preventing absorption and administering NAC when indicated. The efficacy of activated charcoal (AC) for altering outcome is not known but there is evidence that early administration of a single dose of AC given within 2 hours after ingestion may decrease measured plasma APAP concentrations (9), the single metric relied on for the determination of the need for therapy in most cases (4). Beyond this time frame, there is no indication for the use of AC. Gastric lavage should not be used (10).

Patients with a potentially toxic plasma APAP concentration should receive NAC (3), which is metabolized to the amino acid cysteine, a precursor of glutathione. NAC also enhances APAP sulfation, potentially leaving less APAP available to the hepatic P450 system (see Fig. 302.1). NAC is almost 100% effective in preventing APAP toxicity if it is started within 8 hours of the ingestion, regardless of the plasma APAP concentration (3). Delay in starting therapy beyond this time results in a progressive diminution of its efficacy (3,11). If a plasma APAP concentration is unavailable within 8 hours after ingestion, a history (or suspicion) of APAP overdose is sufficient to warrant starting NAC therapy until the plasma APAP levels are known. If APAP is present and the time of ingestion is

unknown, or LFTs are abnormal as a possible result of APAP poisoning, NAC therapy should be instituted regardless of the APAP level.

Two protocols are now used for the treatment of APAP overdose (Table 302.3). For both, it is necessary to treat patients with NAC until plasma APAP concentrations are undetectable, transaminase levels are normal or falling, and PT/INR are normalizing. The duration of NAC therapy using these criteria is frequently <24 hours. In most cases, oral and intravenous routes of administration have equal efficacy (11).

TABLE 302.3
US FDA-Approved Protocols for N-Acetylcysteine Administration

Route of Administration	Loading Dose (mg/kg)	Subsequent Doses	Comments
Oral	140	70 mg/kg q4h	Although this is approved as a 72-hr protocol in most instances, it is stopped early; see text for suggested stopping criteria
Intravenous	150	50 mg/kg over 4 hrs, followed by 100 mg/kg over 16 hrs	Although this is approved as a 20-hr protocol, often it is stopped early; see text for suggested stopping criteria

Intravenous NAC was in widespread use even before its approval for use in 2004 and was also the standard therapy outside the United States. Although NAC given intravenously is easier to administer than the oral preparation, IV administration may be associated with anaphylactoid reactions (primarily itching and rash but also bronchospasm and hypotension). Anaphylactoid reactions are more common when NAC is administered by the IV route. These are generally self-limiting and generally not life-threatening. If serious reactions occur during IV therapy, further NAC treatment can be

given orally. However, if the reaction was minor, or if it is infeasible to use the oral route, it is very reasonable, and common, to continue with IV dosing at a slower infusion rate. The likelihood of such anaphylactoid reactions appears to be inversely proportional to the plasma APAP concentration and may be related to the rate of NAC infusion.

The major practical error with continuous IV infusion of NAC occurs when a patient receives the loading dose in the emergency department (ED) but the maintenance infusion is delayed for some period, often because the patient is being transferred to the ward. Although there is inadequate literature addressing this specific circumstance, based on NAC's 5.6 hour half-life, the author recommends that the entire IV loading dose be re-administered prior to starting the maintenance infusion if more than 5.5 hours has passed since the end of the loading dose.

Giving oral NAC can be challenging because it tastes and smells like rotten eggs and is poorly tolerated. NAC is available as the mucolytic agent Mucomyst® in a 10% or 20% solution. Before administration, it can be diluted to 5% in a soft drink to increase its palatability. It is also helpful to have the patient drink it through a straw from a closed container to prevent the unpleasant odor from causing gagging or emesis. Adding ice is helpful as it decreases the vapor pressure, and therefore the odor, of NAC. Emesis after NAC ingestion is common; the dose should be repeated in full if emesis occurs within an hour of the dose. Standard antiemetics such as metoclopramide (Reglan; 0.1 to 1.0 mg/kg), promethazine (Phenergan; 12.5 to 25 mg), or the 5HT3 antagonist dolasetron (Anzemet; 0.35 mg/kg up to 12.5 mg) may be given and repeated as necessary. Dolasetron may increase the QT interval and thus should be used with caution in patients with cardiac conduction abnormalities, hypokalemia, or hypomagnesemia. It may be best to avoid granisetron and ondansetron because of their association with hepatotoxicity. If emesis continues, IV instead of oral NAC administration can assure adequate and timely therapy.

Infants and small children are dosed with the same dose (in mg/kg) of NAC, however, it is administered in a smaller volume.

Weight-based dosing instructions are provided with the package insert. APAP crosses the placenta, so when a pregnant patient overdoses on APAP, fetal hepatotoxicity is possible. However, NAC also appears to cross the placenta. If spontaneous delivery occurs while the mother is being treated, NAC may be given to the newborn. However, the necessity for NAC administration to neonates has not been established because their immature P450 system may not produce significant quantities of NAPQI.

The management of patients with APAP-induced hepatic or renal failure consists of NAC and supportive care. Intravenous NAC is efficacious in patients with FHF (12). With a first pass effect, the liver may receive a greater dose of NAC when given orally, however, there are no clinical trials supporting the use of oral NAC in FHF. Patients who appear to have FHF may be candidates for transplantation. However, transplantation should not be done simply on the basis of elevated transaminases, because this does not necessarily portend a poor prognosis. The most commonly used transplantation criteria are given in Table 302.4.

TABLE 302.4
Transplantation Criteria for Patients with APAP-Induced Fulminant Hepatic Failure

Arterial pH <7.25–7.30 after adequate fluid resuscitation OR all of the following:
Prothrombin time of >100–180 sec, AND
Serum creatinine >3.4 mg/dL, AND
Grade III–IV encephalopathy

In contrast, low-risk patients can be treated safely in an ED-based observation unit. Patients can be classified as low risk if their ALT is normal and they do not have significant co-ingestants or comorbidities.

CRITICAL INTERVENTIONS

- Obtain a plasma APAP concentration on all patients with a known or suspected drug overdose or hepatotoxicity of unknown cause.

- Administer NAC if the APAP concentration is potentially toxic by the nomogram, if APAP is present and the time of an acute overdose is unknown, or if the APAP concentration is ≤ 10 μg/mL or hepatic transaminases are abnormal after chronic excessive dosing.
- Administer the initial dose of NAC within 8 hours of ingestion.

DISPOSITION

Any patient who has a potentially toxic APAP level by the nomogram requires treatment. Patients who present more than 24 hours after acute APAP ingestion or who have taken repeated supratherapeutic doses and have abnormal LFTs, or plasma APAP concentrations ≤ 20 μg/mL receive NAC therapy. All intentional overdose patients should undergo a psychiatric evaluation before discharge.

Common Pitfalls

- Failing to consider an occult APAP overdose in patients with intentional overdose, chronic pain, or unexplained elevation of hepatic transaminases.
- Starting the loading dose of the IV protocol in the ED without assuring the start of the maintenance doses as soon as the loading dose is completed.

CHAPTER 303
Salicylates

Vinodinee L. Dissanayake and Steven E. Aks

In ancient times, Hippocrates treated fever and pain with willow bark. Its active ingredient, salicin, would be extracted in 1829 to derive the salicylates (1). In 2011, American poison centers reported 39 deaths from ~30,000 cases involving salicylates (2); however, this is likely an underestimate of true salicylate exposure. There are many sources of salicylate in over-the-counter products and complementary medicine, making it highly accessible to the unwitting consumer (Table 303.1) (2,3). Additionally, salicylate poisoning is misdiagnosed and mistreated with considerable frequency. In-hospital mortality increases threefold if the diagnosis of salicylate poisoning is delayed and not made in the emergency department (1).

TABLE 303.1
Nonaspirin Sources of Salicylate

Formulation (Brand Name)	Percentage of Salicylate
Aspirin	75
Bismuth subsalicylate (Pepto-Bismol)	37
Choline and magnesium salicylate (Trilisate)	76
Choline salicylate (Arthropan)	56
Homomenthyl salicylate (sunscreen)	51
Magnesium salicylate (Doan, Magan)	90
Methyl salicylate (oil of wintergreen)	89
Salicylic acid (topical keratolytic)	100
Salicylsalicylic acid (Disalcid, Salsalate)	96
Sodium salicylate (Pabalate)	84

eTABLE 303.1
Elimination of a Single Dose of Salicylic Acid

Pathway	Product(s)	Percentage
Conjugation with glycine	Salicyluric acid	75[a]
Conjugation with glucuronic acid	Salicyl phenolic glucuronide	10[a]
	Salycylacyl glucuronide	5
Oxidation (hydroxylation)	Gentisic acid	1
Urinary excretion	Salicylic acid	10

[a]Saturable pathways.

Salicylates are classified into two groups: (1) phenolic esters (aspirin) and (2) carboxylic acid esters (methyl salicylate). The clinical presentations of overdose are similar though the absorption and potency differ. Aspirin is available in tablet, capsule, and suppository formulations, often over-the-counter and in combination with prescription anticholinergic, antihistamine, muscle-relaxing, and narcotic agents (2). The recommended analgesic, anti-inflammatory, and antipyretic dose is 10 to 15 mg/kg every 4 to 6 hours, not to exceed 80 mg/kg/d. Aspirin acts by irreversibly inhibiting cyclo-oxygenase (COX), also known as prostaglandin G/H synthase, which converts arachidonic acid to prostaglandins and thromboxanes. Analgesic, anti-inflammatory, and antipyretic effects result from inhibition of the COX-2 isoform, which is induced by a variety of inflammatory mediators and suppressed by glucocorticoids. Inhibition of prostacyclin synthesis and resulting accumulation of lipoxygenase causes increased alveolar membrane permeability and pulmonary edema (3). Gastric inflammation and ulceration, decreased renal blood flow, and glomerular filtration are mediated primarily by the COX-1 isoform, present in platelets, endothelium, gastric mucosa, and the kidney. Much lower dose (e.g., 80 mg/d) is needed to inhibit platelet aggregation (3), prolonging the bleeding time for up to 1.5 weeks. Prothrombin time may also be prolonged due to decreased synthesis of clotting factors VII, IX and X.

Aspirin is a weak acid (pK_a 3.5) and because it is mostly nonionized at gastric pH (4), absorption primarily occurs in the small intestine, where it is rapidly hydrolyzed by plasma esterases to

the active metabolite salicylic acid. Pharmacologic effects begin within 30 minutes of ingestion, peak in 1 to 2 hours, and last for about 4 hours. High therapeutic levels are achieved only with chronic dosing. Salicylic acid is extensively bound to serum proteins at low or therapeutic levels and has low protein binding at higher concentrations. High protein binding and predominance of the ionized form results in a small volume of distribution (0.2 L/kg). It is primarily eliminated by hepatic metabolism to inactive metabolites that are excreted in the urine, with a half-life of 2 to 3 hours (eTable 303.1). Salicylate readily crosses the placenta and enters breast milk, but fetal or infant elimination may be prolonged due to immature metabolism and clearance. Liver and renal failure patients have inefficient aspirin elimination as well.

Even though significant clinical and/or laboratory evidence of toxicity is not evident, salicylate levels may be quite high within the first 18 hours of an acute overdose. Conversely, minimally elevated or even therapeutic salicylate levels may be seen with severe poisoning after chronic overdose or late presentations of acute overdose (5). Delayed toxicity may result from pharmacobezoar formation or salicylate-induced pylorospasm. Hence, the severity of poisoning is based on clinical and metabolic findings, not on the salicylate level (1,5). Salicylate poisoning may occur with topical (skin or gum) application of methyl salicylate or salicylic acid, as well as in neonates exposed to therapeutic doses of aspirin and breast-fed infants.

The two main pathways of hepatic metabolism (conjugation; see eTable 303.1) become saturated when salicylate levels are elevated and elimination moves from first-order (proportional to the level) to zero-order (constant) kinetics (6). Hence, with chronic dosing, the salicylate “half-life” increases to 6 to 12 hours; small increases in dose causes proportionately greater increases in serum and tissue salicylate levels, facilitating chronic salicylate toxicity. For the same reason, the salicylate “half-life” may triple after a large acute overdose.

When hepatic metabolism becomes saturated, urinary excretion becomes the major route of salicylate elimination (6). The amount

of excreted salicylate depends on the balance between glomerular filtration of nonionized salicylate, active proximal tubular secretion of ionized salicylate, and passive distal tubular reabsorption of nonionized drug. Augmenting urine flow increases glomerular filtration and tubular secretion while decreasing reabsorption (1). Raising the urine pH decreases reabsorption by converting urinary salicylate to the ionized, nondiffusible form (ion trapping) (4). Raising the serum pH also increases the ionized fraction and limits tissue distribution. Alkaline diuresis increases the renal elimination of salicylate by a factor of 20 or more (1). Conversely, low urine output and pH, which may occur with fever, dehydration, and aciduria, decreases salicylate excretion.

The mechanisms underlying salicylate poisoning are complex and self-perpetuating. When salicylate concentrations exceed therapeutic levels, direct stimulation of the medullary chemoreceptor trigger zone and respiratory center causes vomiting and hyperventilation (respiratory alkalosis), respectively (1). Vomiting may occur shortly after salicylate ingestion as a consequence of direct gastric irritation, and increased carbon dioxide production may contribute to respiratory stimulation. These effects result in dehydration, not only from insensible fluid losses, but also from the bicarbonate diuresis that occurs as a compensatory response to hyperventilation-induced alkalemia (1). Because sodium and potassium are excreted with bicarbonate, there is depletion of these electrolytes (3). Alkalosis may also cause functional hypocalcemia (decreased ionized calcium) with cardiac irritability, tetany (7), and seizures.

As toxicity progresses, the accumulation of intracellular salicylate causes uncoupling of mitochondrial oxidative phosphorylation, inhibition of Krebs cycle enzymes (aminotransferases and dehydrogenases) and amino acid metabolism, and stimulated gluconeogenesis, glycolysis, and lipid metabolism (1,3). These derangements result in increased but ineffective metabolism, with increased body temperature, increased glucose, lipid, and oxygen consumption, and increased amino acid, carbon dioxide, glucose, ketoacid (acetoacetic and β-hydroxybutyric), and lactic and pyruvic acid production. The accumulation of these organic acids, with a

small additional contribution from salicylic acid and its metabolites, leads to an increased anion-gap metabolic acidosis (1). The associated diaphoresis, fever, and osmotic diuresis cause further electrolyte and fluid losses and consequent dehydration (6,7). The renal excretion of organic acids results in aciduria, preventing elimination.

When high salicylate levels are sustained, progressive metabolic derangements and increasing levels of organic acids may cause increased pulmonary capillary permeability, central nervous system (CNS) and respiratory depression, cerebral and pulmonary edema, cardiovascular collapse, and acute renal failure (acute tubular necrosis) (1,3,8,9).

CLINICAL PRESENTATION

Most aspirin toxicity presents after a (1) large acute overdose or (2) after multiple, often inadvertent chronic dosing errors. Mild salicylate poisoning is characterized by respiratory alkalosis (Table 303.2). It typically develops 3 to 8 hours after acute overdose but can occur days after chronic overdose (3). Levels approximate 40 to 80 mg/dL acutely but are lower in chronic poisoning and may be 20 to 30 mg/dL (4). Patients may have nausea, vomiting, abdominal pain, headache, hearing loss, tinnitus (may occur at therapeutic levels), tachypnea and/or hyperpnea, ataxia, dizziness, agitation, and lethargy (1). Mild to moderate dehydration is invariably present. Minor shifts in serum glucose, potassium, and sodium levels are common, but blood urea nitrogen (BUN), creatinine, sodium, and potassium levels often remain normal despite total body fluid and electrolyte deficits.

TABLE 303.2
Stages of Salicylate Poisoning

Stage/Severity	Plasma pH	Urine pH
Early/mild	>7.4	>6
Intermediate/moderate	≥7.4	<6
Late/severe	<7.4	<6

Moderate poisoning, usually associated with levels of 80 to 100 mg/dL acutely or 30 to 40 mg/dL in a chronic case (4), is characterized by metabolic acidosis with respiratory alkalosis, alkalemia, and "paradoxical" aciduria (see Table 303.2). It occurs 6 to 18 hours after an acute overdose and days after chronic overdose. Gastrointestinal (GI) effects persist, and dehydration and neurologic symptoms become more pronounced. Fever, asterixis, diaphoresis, deafness, pallor, confusion, slurred speech, disorientation, hallucinations, tachycardia, tachypnea, and mild or orthostatic hypotension may be present (1). Although patients may appear agitated and combative, it is important not to blunt their respiratory drive with sedative agents, as this could worsen their acidemia (9). Leukocytosis, thrombocytopenia, increased or decreased glucose and sodium levels, hypokalemia, hypocalcemia, and increased BUN, creatinine, ketone, and lactate levels may be seen on laboratory evaluation.

Severe acute salicylate poisoning, associated with levels >100 mg/dL acutely or >40 mg/d in a chronic overdose, is dangerous (4), and is characterized by an increased anion-gap metabolic acidosis, acidemia, and aciduria (see Table 303.2). It usually develops 12 to 24 hours after acute overdose and longer after chronic overdose. Hyperventilation (respiratory alkalosis) or hypoventilation (respiratory acidosis) and hypoxemia may be present. Other manifestations include coma, seizures, cerebral edema, papilledema, respiratory depression, hypothermia or hyperthermia, hypotension, pulmonary edema, congestive heart failure, dysrhythmias, and profound dehydration with oliguria (1,3). The chest radiograph may show noncardiogenic pulmonary edema, and brain CT scan may reveal cerebral edema. Electrocardiographic abnormalities may result from direct cardiotoxicity, electrolyte

abnormalities, or co-ingestants. Sinus tachycardia is common. Asystole is the most common cause of cardiac arrest, but ventricular tachycardia and ventricular fibrillation may also occur.

Pediatric poisonings tend to advance faster than those in adults, whereas adults are more prone to pulmonary complications (1). Morbidity is higher when the diagnosis is delayed and with chronic more than acute poisoning. Although the overall mortality is $<0.01\%$, fatality rates of 15% to 50% occur with severe poisoning. Some neurologic dysfunction may persist in those who recover from severe poisoning.

DIFFERENTIAL DIAGNOSIS

Increased anion-gap metabolic acidosis is seen in only 15% to 20% of adults with salicylate poisoning. Metabolic acidosis with respiratory alkalosis is seen in 50% to 61% of poisoned adults. Respiratory alkalosis is the sole acid–base disturbance in 20% to 25%, and a combined respiratory and metabolic acidosis is seen in 5%. Metabolic acidosis is more common and respiratory alkalosis is less common or absent in children, in patients with large acute ingestions, chronic intoxication, and delayed treatment.

Salicylate poisoning should be considered in any patient with an unexplained anion-gap acidosis. The diagnosis is initially missed in 25% to 60% of patients, particularly those chronically taking the drug. These patients are often elderly, take nonaspirin salicylates, and have underlying medical problems (3). Patients with chronic overdoses, classically present confused or unresponsive with increased temperature, dehydration, hypotension metabolic acidosis, and respiratory alkalosis. Often, these signs are mistaken for sepsis but signs and symptoms of salicylate poisoning have been mistakenly attributed to anxiety, cardiopulmonary disease, cerebrovascular disease, chronic obstructive pulmonary disease, dementia, encephalopathy, alcohol intoxication, ketoacidosis, withdrawal, viral encephalitis, meningitis, pancreatitis, psychiatric disorders, and sepsis (4). These patients require a thorough workup for other causes of altered mental status.

Salicylate poisoning in children may be indistinguishable from Reye syndrome. A low (subtherapeutic) cerebrospinal fluid salicylate level, high serum alanine, glutamine, and lysine levels, and fatty infiltration of the liver indicate Reye syndrome rather than salicylate poisoning. Salicylate poisoning may also be confused with inborn errors of metabolism as well.

Other causes of anion-gap metabolic acidosis include toxic alcohols, ketosis, and lactic acidosis associated with hypoxia, seizures, or shock. Salicylate poisoning may be ruled out in a patient who has persistently normal arterial blood gas (ABG) and serum electrolytes but is symptomatic many hours after an unknown overdose.

ED EVALUATION

The history should include the time(s), amount(s), and formulation of salicylate ingested. The physical examination should focus on vital signs, neurologic status, and cardiorespiratory function. Ensuring accurate measurement of the respiratory rate, temperature, and degree of dehydration is essential (1). Papilledema, peritoneal signs, and occult blood in vomitus and stool should be identified.

Aspirin products are frequently confused with acetaminophen and vice versa (2). Unless the product is available for identification or a third party confirms history, serum levels of both drugs should be obtained when the ingestion of either is reported, particularly in those with intentional overdose.

Because of delayed and prolonged absorption, if salicylate levels are elevated, they should be checked repeatedly until levels are declining. A nontoxic salicylate level soon after ingestion does not rule out a significant overdose, particularly with enteric-coated or sustained-release formulations (4). If the patient is symptomatic or the salicylate level is elevated, then testing should include ABG analysis, serum electrolytes, glucose, BUN, creatinine, and urinalysis. If acid–base abnormalities are present, further evaluation should include serum calcium, magnesium, ketone, and lactate levels, liver function tests, complete blood count, coagulation

profile, ECG, and chest radiograph (1,3). If levels continue to rise, repeat metabolic reevaluation is necessary.

KEY TESTING

- Serum salicylate
- Acetaminophen level for intentional ingestions
- Blood gas analysis
- Serum electrolytes
- Urinalysis and urine pH
- Electrocardiogram
- Chest radiography for possible pulmonary edema
- Additional tests: serum calcium, magnesium, lactate, liver enzymes, and head CT for decreased level of consciousness and possible cerebral edema

ED MANAGEMENT

Patients with salicylate poisoning may present after acute ingestion or have chronic exposure leading to more subtle presentations. In either case, advanced life-support measures should be instituted when indicated. When patients require endotracheal intubation, maintaining hyperventilation before, during, and afterwards is critical because losing the respiratory alkalosis worsens acidemia and enhances toxicity. Since artificial ventilation is associated with increased airway resistance and dead space, mechanical hyperventilation will be less effective than spontaneous hyperventilation (1,5). Therefore, sodium bicarbonate ($NaHCO_3$), 1 to 2 mEq/kg over 5 minutes, is suggested at the time of induction for patients with acidemia or a pCO_2 less than 20 mm Hg. ABGs should be checked after intubation and after sodium bicarbonate therapy.

Because CNS hypoglycemia may occur despite a normal serum glucose in patients with salicylate poisoning, D50 (50 mL) should be given to those with altered mental status, unless the glucose level is elevated (1). Seizures should be treated with benzodiazepines and barbiturates and supplemental glucose. It is also advisable to

administer $NaHCO_3$ (0.5 mEq/kg IV over 2 to 5 minutes) as acidemia worsens after a seizure. Patients who are unresponsive or postictal may have cerebral edema and may benefit from head elevation, hyperventilation, and possibly mannitol, furosemide, and dexamethasone. Diuretics should be used cautiously since patients often have hypovolemia.

The degree of dehydration is often underestimated. Volume deficits of 2, 4, and 6 L (20, 40, and 60 mL/kg in children) are typical with mild, moderate, and severe poisoning, respectively. IV fluid can be given as 5% dextrose solution with three 50-mL ampules of $NaHCO_3$ added to each liter (1). With hypernatremia, a more hypotonic solution should be used. The use of a dextrose-containing solution is important because of the potential for occult CNS hypoglycemia. Cerebral or pulmonary edema should be monitored closely in those with renal dysfunction. Monitoring urine output is helpful for assessing rehydration.

Central venous pressure monitoring or ultrasonography of inferior vena cava collapse may guide treatment for hypotension or oliguria, especially if there is evidence of heart failure or pulmonary edema. Congestive heart failure should be treated accordingly, but patients with noncardiac pulmonary edema should be treated with positive end-expiratory pressure rather than diuretics. Preventing increased acidemia by maintaining hyperventilation is critical in patients with compromised pulmonary function (1,5).

Hyperthermia should be treated with cooling blankets, ice packs, and evaporative methods. Acetaminophen and NSAIDs should be avoided. The presence of peritoneal signs necessitates surgical evaluation. Vitamin K should be given for coagulation abnormalities. Underlying metabolic derangements should be corrected. Insulin is not needed for nondiabetics with hyperglycemia and may be dangerous, particularly if there is coexisting hypokalemia. Hyperkalemia does not usually require specific therapy and will likely resolve with fluid administration and correction of acidosis. Paper-bag breathing or sedatives for the

treatment of agitation is not recommended because an increase in the pCO_2 can worsen concomitant acidemia.

ACUTE SALICYLATE POISONING CONSIDERATIONS

GI decontamination with single-dose activated charcoal is recommended for patients with accidental ingestions of >150 mg/kg and in all patients with intentional overdoses. Although early activated charcoal decontamination is ideal, late administration may still prevent absorption since salicylates can form concretions. If the amount ingested is known, the dose of activated charcoal is a 10:1 ratio (activated charcoal:salicylate) (5). For unknown ingested quantities, children may be given 10 to 25 g and adults may be given 50 to 100 g.

Multidose activated charcoal (MDAC) may not only decrease continued absorption, especially when salicylate levels continue to rise, but may also enhance elimination. Although not associated with a mortality benefit, MDAC may shorten the salicylate half-life after acute overdose and is recommended for those with a salicylate level >30 mg/dL, when metabolic pathways are saturated and toxicity is present (6). The optimal dosing and frequency for MDAC administration is controversial, though a reasonable approach is 50 g orally every 2 to 4 hours as long as the patient is hemodynamically stable with bowel sounds and the mental status to tolerate it (1).

Orogastric lavage may help decontaminate large salicylate ingestions, but the risks associated with this procedure are thought to usually outweigh the benefits (1,8). Whole-bowel irrigation is popular for patients with large ingestions of enteric-coated or sustained-release preparations (1), however its efficacy is unproven. Serial salicylate levels should be obtained to assess the efficacy of GI decontamination. Decontamination of the skin is warranted for exposure to topical salicylates (1).

Other methods of enhanced elimination include urinary alkalization and dialysis. Urinary alkalization may shorten the salicylate half-life to 6 to 12 hours (7) in acute overdose with

salicylate levels <70 mg/d by decreasing tubular salicylate reabsorption (7). Indications are the same as those for MDAC. The goal is a urine pH of ≤ 7.5 with a brisk (3 to 6 mL/kg/hr) urine output. Although counterintuitive, this is still indicated during early or mild intoxication, when the serum and urine pH are both alkaline, because respiratory alkalosis with compensatory renal bicarbonate and fluid excretion account for these findings. If left untreated, this can lead to dehydration and more severe metabolic acidosis later. Urinary alkalization is ineffective if hypokalemia is present, which is thought to occur when hydrogen ions shift into cells and potassium shifts out. Potassium supplementation is usually necessary because patients are commonly potassium-depleted, especially in the presence of acidemia (approximately 0.6 mEq/L for each 0.1 U decrease in pH). As a general guideline, 10 to 20 mEq of potassium will be necessary for each 50 mEq of $NaHCO_3$ administered. Acetazolamide should not be used because it can cause acidemia by increasing the ionized drug fraction and CNS salicylate levels (4).

Complications of $NaHCO_3$ administration include excessive alkalemia, hypocalcemia, hypokalemia, hypernatremia, and fluid overload with cerebral and pulmonary edema, particularly in the elderly and with severe poisoning (3). Cardiac monitoring, frequent evaluation of vital signs, mental status, cardiorespiratory function, urine output, and laboratory parameters (ABG analysis, serum calcium, and electrolytes) should be performed during and after such therapy. Relative contraindications for $NaHCO_3$ include oliguric renal failure, congestive heart failure, and cerebral or pulmonary edema. In these situations there should be a lower threshold for the initiation of hemodialysis; in fact, it is likely that hemodialysis is underutilized in salicylate poisoning (4,6,8).

Hemodialysis may shorten the salicylate half-life to 2 to 3 hours. Peritoneal dialysis, exchange transfusion, and other methods of extracorporeal removal are less effective and should be used only if hemodialysis is unavailable, contraindicated, or technically impossible (e.g., in infants or in patients with active or recent

bleeding complications) (4). Clinical indications for hemodialysis include confusion, disorientation, coma, seizures, cerebral or pulmonary edema, renal failure, and clinical or metabolic deterioration despite other therapies (6,8). Patients with serum salicylate levels greater than 100 mg/dL in acute overdose (5) may require hemodialysis regardless of symptoms. Acidemia and body temperature $>38^{\circ}C$ are associated with high mortality and should prompt consideration for hemodialysis. Toxicity that progresses or fails to improve with other treatment (e.g., those with comorbidities or limited reserve) should be considered for hemodialysis even if salicylate levels are not markedly elevated (1).

In contrast to the usual dialysis patient with chronic renal failure, those with salicylate poisoning are often hemodynamically compromised because of underestimated or undertreated dehydration and cardiac dysfunction. As such, they are prone to cardiovascular decompensation on initiation of hemodialysis (5). Hypotension is common and ventricular dysrhythmias are considered premorbid events. Priming the dialysis circuit with normal saline and administering a fluid bolus prior to and during dialysis are recommended as prophylactic measures, along with correction of volume deficits and metabolic abnormalities. The dialysate bath should contain bicarbonate (32 mEq/L) to treat and prevent acidemia and to enhance the removal of salicylate.

Clinical improvement with decreasing salicylate levels is the endpoint of therapy. Once the salicylate level has reached 30 mg/dL, first-order kinetics resume. In patients with very high levels or ongoing absorption from a gastric bezoar, levels may rise after an initial decline (8). Repeat levels ensure that toxicity does not recur after dialysis.

CHRONIC SALICYLATE POISONING CONSIDERATIONS

GI decontamination will not benefit the patient who presents with chronic salicylate exposure. The slower rise in serum salicylate level has allowed the drug to affect its target organ, the brain. Unlike acute intoxication where the tissue levels lag behind serum levels, in

chronic exposure the tissue level will be in equilibrium with serum levels so toxicity occurs with lower serum levels. Seizures are common with serum levels of 40 mg/dL. Urinary alkalization is of little benefit since serum salicylate concentrations are relatively low, urine levels are low, and many of these patients have pulmonary or cerebral edema that may preclude large doses of bicarbonate. Hemodialysis is much more important in these patients, as their mental status is a better marker of toxicity than their serum levels. Hemodialysis is warranted in chronically exposed patients with serum salicylate levels >60 mg/dL, regardless of symptomatology.

CRITICAL INTERVENTIONS

- Maintain hyperventilation during and after endotracheal intubation.
- In patients with acidemia, administer $NaHCO_3$ prior to intubation.
- Replace volume deficits with intravenous fluids containing dextrose and saline.
- Alkalinize the urine with intravenous $NaHCO_3$ and correct hypokalemia.
- Perform frequent clinical and laboratory reevaluation and obtain serial salicylate levels.
- Consider hemodialysis for patients with confusion, seizures, uncorrected acidosis, cerebral edema, pulmonary edema, acute level >100 mg/dL and chronic level >60 mg/dL, progressive deterioration despite other treatments or early evidence of volume overload.
- Give activated charcoal in large acute overdose.

DISPOSITION

Patients with only tinnitus and GI symptoms and easily corrected acidosis after acute overdose can often be treated in an observation setting if 1) the peak salicylate level is <60 mg/dL after aggressive treatment, and 2) the level is decreasing. Patients with chronic poisoning, higher levels, underlying medical problems, and

moderate or severe toxicity should be admitted to an intensive care unit. A nephrologist should be alerted about severe poisonings for hemodialysis. Patients with severe poisoning or moderate poisoning with high (or rising) salicylate levels should be transferred to a facility in which hemodialysis is available.

Common Pitfalls

- Failure to consider salicylate ingestion and obtain a salicylate level for unexplained acidemia, particularly with altered mental status.
- Failure to obtain salicylate and acetaminophen levels in those reporting overdose of either.
- Failure to obtain repeat salicylate levels to detect delayed absorption.
- Failure to suspect chronic salicylate poisoning in ill and/or elderly patients..
- Failure to monitor for complications of salicylate poisoning and its treatment.
- Overvigorous bicarbonate or saline contributing to pulmonary or cerebral edema.
- Basing treatment only on drug levels instead of clinical and laboratory findings.
- Failure to match pre-intubation and post-intubation tidal volume, resulting in severe acidemia.

CHAPTER 304

Nonsteroidal Anti-Inflammatory Drugs

Marco L.A. Sivilotti

Nonsteroidal anti-inflammatory drugs (NSAIDs) are a heterogeneous group of agents that have anti-inflammatory, analgesic, and antipyretic activity. There are a variety of NSAIDs, which can be classified by target specificity and structure (Table 304.1). With widespread use and over-the-counter availability, it is not surprising that NSAIDs constitute one of the most common medications encountered in intentional overdose. Three-fourths of these ingestions involve ibuprofen, the first nonsalicylate NSAID to be approved for over-the-counter use in the United States. Despite their frequency, most NSAID overdoses result in minimal symptoms, and death is rare. Major complications such as gastrointestinal (GI) bleeding during therapeutic use are a much greater health problem.

TABLE 304.1
Pharmacokinetics of NSAIDs after Therapeutic Doses

Drug	Brand Name	Time to Peak Level (hrs)	Half-life (hrs)	Maximum Daily Adult Dose (mg)
Nonselective COX inhibitors				
Acetic acids				
Diclofenac sodium	Voltaren	2–3	1.2–1.8	225
Diclofenac potassium	Cataflam	0.3–2.0	1.2–1.8	150
Etodolac[a]	Lodine	1–2	7.3	1,200
Indomethacin[a–c]	Indocin	1–2	4.5–6.0	200
Ketorolac[c]	Toradol	0.5–1.0	2.4–8.6	IM 120; PO 40
Nabumetone[d]	Relafen	2.5–4.0	22–30	2,000
Sulindac[e]	Clinoril	1–2	7.8	400
Tolmetin	Tolectin	0.5–1.0	1.1–1.5	2,000
Fenamic acids				
Mefenamic acid	Ponstel	1–3	2–4	1,000
Meclofenamate	Meclomen	0.5–2.0	2	400
Oxicams				
Meloxicam[f]	Mobicox	5–6	20	22.5
Piroxicam	Feldene	3–5	30–60	20
Propionic acids				
Fenoprofen	Nalfon	1–2	2–3	3,200
Flurbiprofen	Ansaid, etc.	1–2	3–4	200
Ibuprofen[b]	Motrin, Advil, Nuprin	0.5–2.0	1.8–2.5	3,200
Ketoprofen[a]	Orudis, etc.	0.5–2.0	1.5–4.0	300
Naproxen[a,b]	Naprosyn, Aleve	2–4	12–15	1,500
Naproxen sodium[a]	Anaprox	1–2	12–15	1,375
Oxaprozin	Daypro	3–5	42–50	1,800
Carprofen	Rimadyl			1,200
Pyrazolones				
Oxyphenbutazone	Oxalid			27–72
Phenylbutazone	Azolid, Butazolidin	1–4	50–100	600
Salicylates				
Acetylsalicylic acid	Aspirin, etc.	1–2	2–30	4,000
Diflunisal	Dolobid	1–2	5–20	1,500
Selective COX-2 inhibitors				
Celecoxib	Celebrex	2–4	11	400
Rofecoxib	Vioxx	2–3	17	50
Parecoxib	Dynastat	2 (IM)	8	IV/IM 40
Valdecoxib	Bextra	8		40
Etoricoxib	Arcoxia		22	120

[a]Available as a sustained-release product.
[b]Available as a liquid formulation.
[c]Also available as parenteral formulation.
[d]Prodrug metabolized to 6-methoxy-2-naphthylacetic acid.
[e]Prodrug metabolized to sulindac sulfide (half-life 16.4 hours).
[f]Preferential COX-2 inhibitor but selectivity lost at therapeutic doses.

The primary pharmacologic effects of NSAIDs result from the inhibition of cyclooxygenase (COX), the enzyme family involved in the initial step of prostaglandin (PG) synthesis. Two isoforms, termed COX-1 (constitutive) and COX-2 (inducible), have been identified. Because the anti-inflammatory properties of NSAIDs result primarily from COX-2 inhibition, NSAIDs with selective COX-2 inhibition were developed with the promise of fewer side effects (1), but some of these agents were subsequently withdrawn due to increased cardiovascular risk. In overdose, selectivity for COX-2 may be lost, and the acute toxicity resembles that of nonselective NSAIDs.

Inhibition of COX shunts arachidonic acid to leukotrienes, at times precipitating severe allergic reactions. The adverse GI effects of gastritis and ulceration result from the inhibition of PGD_2, PGE_2, and PGF_2, which maintain the gastric mucosal barrier, and direct irritation. Acute renal failure with salt and water retention is attributed to inhibition of PGI_2 and PGE_2, which have vasodilatory and natriuretic activity in the kidney (2). The cardiovascular toxicity of the selective COX-2 agents appears to result from decreased PGI_2 in the vascular endothelium (COX-2), coupled with minimal effects on platelet thromboxane A_2 (COX-1).

Most NSAIDs are rapidly and almost completely absorbed (3). They are weak acids with pK_a values ranging from 3.5 to 5.6 and have small volumes of distribution (0.08 to 0.4 L/kg) from extensive protein binding (celecoxib, at 6 L/kg, is an exception). Elimination is primarily via hepatic CYP2 C, with subsequent renal excretion of glucuronide conjugates. As much as 50% of ketorolac and 30% of indomethacin is excreted unchanged in the urine (3). Only small quantities ($<10\%$) of other NSAIDs are excreted unchanged in the urine, limiting the efficacy of urinary alkalinization in promoting elimination. Indomethacin, sulindac, etodolac, phenylbutazone, meloxicam, and piroxicam undergo enterohepatic recirculation. The renal clearance of naproxen and oxaprozin is increased at high plasma concentrations owing to saturation of protein binding. Phenylbutazone exhibits dose-dependent Michaelis–Menten elimination. Pharmacokinetic data are summarized in Table 304.1.

Except for pyrazolones and fenamic acids, NSAIDs seldom cause serious toxicity, even in large doses (4). There is inadequate information to determine the minimum toxic or lethal dose for most NSAIDs. In a series of ibuprofen overdoses, all children who ingested <100 mg/kg remained asymptomatic, whereas those who ingested >400 mg/kg were at risk of developing significant toxicity (5). In adults, the correlation between the amount ingested and subsequent development of symptoms was poor, with those ingesting between 6 and 54 g of ibuprofen at risk for potentially serious toxicity (6). In contrast, seizures have been reported with mefenamic acid ingestions

of as little as 2.5 g in a 12-year-old child (4). Phenylbutazone has caused death with as little as 2 g in a 1-year-old child and 2.5 g in an alcoholic adult (4,7).

CLINICAL PRESENTATION

Most patients remain asymptomatic or develop only mild GI or neurologic symptoms following acute overdose. Specific signs and symptoms are summarized in Table 304.2. Death is rare and usually results from secondary complications such as aspiration or sepsis. In the absence of acute renal failure or secondary complications, full recovery can be expected within 6 to 24 hours. The elderly are more likely to develop adverse effects with therapeutic doses and toxicity with overdoses.

TABLE 304.2
Signs and Symptoms of Nonsteroidal Anti-Inflammatory Drug Overdose

Gastrointestinal: nausea, vomiting, anorexia, abdominal pain, diarrhea, gastritis, GI bleeding, occasional hepatocellular injury, rare cholestasis
Neurologic: dizziness, nystagmus, diplopia, blurred vision, headache, tinnitus, restlessness, lethargy, ataxia, confusion, coma, muscle fasciculations, seizures
Respiratory: hyperventilation, respiratory depression with cyanosis, apnea, diaphoresis
Cardiovascular: hypotension, bradycardia, occasional tachycardia, rare cardiac arrest
Renal: sodium retention and edema, proteinuria, hematuria, acute oliguric or nonoliguric renal failure
Hematologic: decreased platelet aggregation, prolongation of prothrombin time and partial thromboplastin time
Other: occasional metabolic acidosis, rare electrolyte imbalance

In contrast, the pyrazolones and fenamic acids can cause severe toxicity. Phenylbutazone and its active metabolite oxyphenbutazone can cause coma, seizures, dysrhythmias, cardiogenic shock, respiratory alkalosis, and metabolic acidosis (4,8,9). Tinnitus, deafness, and a rash may be present. Hepatic necrosis, without other symptoms, may develop 24 hours after overdose. A red discoloration

of the urine caused by the metabolite rubazonic acid may be observed. Mefenamic acid can cause muscle twitching and tonic–clonic seizures within 12 hours of ingestion (4). Respiratory and cardiac arrest may follow seizures.

Propionic and acetic acid derivatives are associated with relatively low toxicity. Of these agents, fenoprofen appears to be the most toxic (4). Metabolic acidosis after ibuprofen overdose is probably caused by high levels of the acidic parent drug and metabolites (10). Indomethacin frequently causes headaches and tinnitus, even at therapeutic doses.

After piroxicam overdose, dizziness with blurred vision and brief coma are reported (4). Because of the long elimination half-life of piroxicam, overdose symptoms can be prolonged. Multisystem toxicity (with GI, neurologic, renal, hepatic, and hematopoietic effects) was noted in a 2-year-old child who ingested 100 mg of piroxicam (11). Prolonged toxicity should be anticipated after overdose of oxaprozin and nabumetone, which also have long half-lives. NSAID plasma levels are not routinely available and are not necessary for the treatment of acute ingestion (5).

DIFFERENTIAL DIAGNOSIS

The diagnosis of NSAID overdose is made on the basis of history and the exclusion of other etiologies. The possibility of acetaminophen, colchicine, and salicylate ingestion should be considered in patients with overdose of an unknown arthritis medication or analgesic.

The central nervous system (CNS) depression that occurs with NSAID overdose is usually mild; coma unresponsive to stimulation is uncommon. Deep coma, marked hypotension, and severe respiratory depression suggest the presence of other drugs. The high anion-gap metabolic acidosis caused by ibuprofen is relatively mild and short-lived compared with that caused by salicylates, ethylene glycol, and methanol (10).

ED EVALUATION

A detailed history including available medications may provide the only clue to NSAID overdose. The amount and time of ingestion and

the onset, nature, and progression of symptoms should be noted. The physical examination should include complete vital signs, oxygen saturation measurement, and assessment of mental status and cardiorespiratory function. Evaluation for occult GI bleeding should be considered for patients with abdominal pain.

Accidental ingestions of a nontoxic dose need no laboratory testing. For symptomatic patients, those with underlying kidney dysfunction, and the elderly, a urinalysis, blood urea nitrogen (BUN) and creatinine, electrolytes and glucose, and perhaps a complete blood count (CBC) should be obtained. Etodolac may cause a false-positive urine bilirubin and a false-positive urine ketone test on dipstick. Although the time of onset of renal failure is poorly defined, urinalysis, serum BUN, and creatinine may be useful in adults who ingest >6 g of ibuprofen (5). Arterial or venous blood gases should be monitored in patients with significant mental status changes or respiratory depression. After pyrazolone overdose, liver function tests should be obtained. As with other ingestions, serum acetaminophen and possibly salicylate concentrations should be measured in patients with intentional overdose. Toxicology screens of urine and blood rarely detect or correctly identify most NSAIDs other than salicylates and are not useful.

KEY TESTING

- There are no specific tests for NSAID overdose.
- Symptomatic patients, those with underlying kidney dysfunction, and the elderly may need a urinalysis, CBC, electrolytes with anion gap, BUN, creatinine, glucose.

ED MANAGEMENT

Management consists of supportive care. The rare severely ill patient may need mechanical ventilation, especially if respiratory acidosis is present. Hypotension can be managed with intravenous crystalloids. Vasopressors are seldom necessary. Benzodiazepines should be given for seizures. Sodium bicarbonate should be given to patients with significant metabolic acidosis. GI bleeding should be treated by

standard measures. Coagulopathy can be corrected by administering fresh-frozen plasma and vitamin K_1.

Activated charcoal should be considered in patients with recent intentional overdose of more than 10 therapeutic doses, and children who present within 4 hours of accidentally ingesting more than 5 adult doses (8). Fenamic acids or pyrazolones may cause serious toxicity with even a twofold overdose, and decontamination is appropriate for all these patients. Multiple-dose activated charcoal (MDAC) therapy has not been studied with most NSAIDs. Although the elimination half-life of therapeutic doses of phenylbutazone was decreased by 30% using MDAC (12), the effectiveness of this treatment is likely to be minimal, even for NSAIDs that undergo enterohepatic recirculation. Because most NSAIDs are highly protein-bound and rapidly metabolized, diuresis or dialysis is not useful, except perhaps for severe phenylbutazone poisoning.

CRITICAL INTERVENTIONS

- Establish intravenous access, initiate cardiac monitoring, and provide supportive care as clinically indicated.
- Consider other ingestions, including acetaminophen and salicylates, in patients with intentional overdose.

DISPOSITION

Most patients will be observed for 4 to 6 hours after ingestion or until minor symptoms resolve and then are discharged (5,8). After the ingestion of fenamic acids or pyrazolones, symptomatic patients should be monitored for at least 12 hours. Patients with coma, respiratory depression, seizures, or renal failure should be admitted to a medical intensive care unit.

Patients with an abnormal urinalysis or underlying renal dysfunction should have follow-up kidney function tests. A CBC and kidney and liver function tests should be repeated 24 to 48 hours after pyrazolone overdose. Follow-up liver function tests should be obtained in symptomatic piroxicam overdose patients.

Transfer would rarely be necessary. If acute renal failure develops, a nephrologist should be consulted. Intentional ingestions should be evaluated for ongoing suicidal risk.

Common Pitfalls

- Failure to consider other ingestions in patients with significant CNS depression, metabolic acidosis, or vital sign abnormalities.
- Failure to consider acetaminophen, salicylate, or colchicine ingestion in patients who overdose on an unknown arthritis medicine.
- Failure to appreciate that phenylbutazone and mefenamic acid can cause serious toxicity after overdose.

ACKNOWLEDGMENT

The author gratefully acknowledges the contributions of Paula L. Townsend as author of this chapter in previous editions.

CHAPTER 305

Opioids

Jerry W. Snow and R. Brent Furbee

The term *opiate* applies to naturally occurring derivatives of opium. *Opioid* originally referred only to synthetic or semisynthetic compounds that exert effects through opioid receptors but increasingly, the term *opioid* applies to both groups. *Narcotic* is an outdated term to describe the effects, used before the mechanism was known. The opium poppy, *Papaver somniferum,* is the source of naturally occurring opioids. Opium contains morphine, codeine, and thebaine, from which natural and semisynthetic opioids are derived. Papaverine (a vasodilator) and noscapine (an antitussive) are nonanalgesics found in opium. The opioid antagonists, naloxone and naltrexone, are semisynthetic derivatives of thebaine.

Opioid prescription abuse is recognized as a growing epidemic. Increased use of opioids for treatment of chronic noncancer pain increased in the 1980s. "Chronic pain" is defined by the International Association for the Study of Pain as "pain that persists beyond normal tissue healing time, which is assumed to be three months" (1). Although it appears logical, the use of hydrocodone, oxycodone, methadone, and other opioids for chronic noncancer pain has increased dramatically despite the lack of evidence supporting its effectiveness. Several epidemiologic studies indicate an increase in methadone-related deaths in the United States. This may be associated with QT_c prolongation and resultant arrhythmias (1). Sales of opioid analgesics increased fourfold between 1999 and 2010, and between 1997 and 2007 the average amount of opioids distributed to persons in the United States jumped from 96 mg of

morphine equivalents/person to 700 mg/person, an increase of over 600% (2). Diversion is also a growing concern. A 2010 National Survey on Drug Use and Health (NSDUH) showed that an estimated 22.6 million, or 8.9% of Americans, aged 12 or older, were current or past month illicit drug users (3).

Since 2003, opioid analgesic deaths have been more than from cocaine and heroin combined (2) and now account for more deaths than suicide or motor vehicle accidents (3). Hydrocodone topped all opioid prescriptions with 136.7 million prescriptions in 2011. Factors that predict drug abuse, misuse, or aberrant drug behavior include personal or family history of drug or alcohol abuse, younger age, or presence of psychiatric conditions (1). Patients who are prescribed doses of $<$100-mg morphine equivalents/day account for nearly 80% of the at-risk population, but only 20% of prescription drug overdoses. Patients receiving high doses ($>$100 mg morphine equivalent/d) or those receiving prescriptions from multiple physicians accounted for about 20% of the at-risk population, but 80% of the overdoses (2). In West Virginia, and Ohio, 25% to 66% of deaths from pharmaceutical overdoses used opioids prescribed for someone else. Opioid analgesic misuse and death are highest among men, persons aged 20 to 64 years, non-Hispanic white, and poor and rural populations as well as patients with mental illness (2).

This “epidemic” is due, in part, to changing attitudes toward pain management. In the late 1990s, state medical boards began to curtail restrictions on laws controlling the prescribing of opioids for chronic noncancer pain. New pain management guidelines such as those by the Joint Commission on the Accreditation of Health Care Organizations (JCAHO) in 2000 recognizing the “right to pain relief” encouraged physicians to be more liberal in their prescribing of opioids. Manchikanti concluded in 2012 that, “It has been speculated that in the coming years, there will likely be an extensive “postmortem” on the massive opioid treatment movement and the escalating social crisis that has accompanied it. It is universally accepted that this massive treatment movement has led to huge collateral damage in terms of diversion, misuse, and abuse of opioids” (3).

MECHANISM OF ACTION

Opioids' clinical effects are the result of complex interactions with the three primary opioid receptor types (mu, delta, and kappa). Three additional receptor types, nociception/orphanin FQ, epsilon, and zeta, are not yet well characterized in humans. The sigma receptor has been reclassified because actions mediated via this receptor are not reversed by naloxone. The mu receptor mediates the majority of clinical effects and most supraspinal analgesic effects as well as sedation and respiratory depression. Delta and kappa receptors act primarily at the spinal cord level. Euphoria is mediated by mu receptors and dysphoria by kappa receptors. These receptors are found throughout the body including the periphery, pre- and postsynaptic sites in the spinal cord, and brain to form an ascending pain transmission system and a descending initiatory system that modulates spinal cord pain transmission (4).

Upon opioid binding, G proteins are activated and use a secondary messenger system involving cyclic AMP to have several effects that produce pain inhibition through (1) blockade of calcium channels, resulting in a decrease of presynaptic neurotransmitter release, and (2) opening potassium channels, producing hyperpolarization of postsynaptic neurons and a decrease in transmission of pain (4). Alpha-2 agonists such as clonidine have some effects similar to opioid receptor binding (see Chapter 322) (5).

Opioid antagonists competitively bind to each type of the opioid receptors and reverse the clinical effect of opioids as well as altering the configuration of the receptor to decrease the availability of receptor sites. Pure antagonists (naloxone, nalmefene, and naltrexone) avidly bind to all major opioid receptor subtypes.

CLINICAL PRESENTATION

The classic opioid toxidrome includes the triad of (1) CNS depression, (2) respiratory depression, and (3) miosis. However, opioids can present with a wide range of clinical findings and atypical presentations (Table 305.1). Opioids are used through

intravenous, intramuscular, intranasal, inhalational, oral, subcutaneous, intradermal, or transdermal routes. Unintentional poisoning in addicts/recreational users typically occurs in novice users, during binging, or when an experienced user obtains an unfamiliar supply of heroin and accidentally miscalculates the dose owing to differences in purity. Intentional suicidal overdose or attempted homicide is also common.

TABLE 305.1
Atypical Presentations of Opioid Poisoning

Agent	Prominent/Atypical Feature
Propoxyphene (Darvon)	Rapid, sudden onset of opioid effects
	Seizures, psychosis (unresponsive to naloxone)
	Hypotension
	Prolongation of PR, QRS, and ventricular tachycardia
	Delayed onset of membrane-depressant effects
	Low dose is life-threatening (11 mg/kg)
	Higher doses of naloxone needed to antagonize narcotic effects
Diphenoxylate (Lomotil)	Initial anticholinergic features
	Delayed onset of opioid effects
	Children at high risk for toxicity
Fentanyl	Chest wall rigidity
	Serotonin syndrome
Meperidine (Demerol)	Mydriasis
	Prolonged half-life of metabolite
	Seizures
	Increased muscle tone; serotonin syndrome
Methadone	QT_c prolongation, torsade de pointes
Pentazocine (Talwin)	Higher doses of naloxone needed to antagonize effects
Tramadol (Ultram)	Seizures unresponsive to naloxone
	Serotonin syndrome

Children usually present with unintentional exposure although iatrogenic poisonings and dosing errors do occur. Overdose in children characteristically has a delayed onset, unexpected severe

toxicity, and prolonged effects. Children may ingest pills or apply/ingest transdermal patches (that sometimes become stuck on the roof of the mouth). Elderly patients, particularly those on opioid therapy for chronic pain control, also represent a high-risk group for unintentional poisoning. Contributing factors include comorbidities, slower metabolism, decreased renal clearance and other age-related physiologic changes, and alterations in body composition.

The onset of symptoms is nearly immediate after injection, inhalation, and nasal insufflation. Although effects are usually noted within 30 minutes of ingestion, absorption can be erratic and delayed, particularly in children and with sustained-release formulations. Lomotil (diphenoxylate and atropine) is notorious for causing delayed toxicity, perhaps because both constituents can inhibit gastrointestinal motility. The effects of transdermal medications also begin about 30 minutes after application and can develop or progress after the patch is removed. Intravenous injection and oral ingestion of fentanyl patches delivers the entire drug content of the patch at one time rather than the ongoing absorption of small aliquots of fentanyl.

Respiratory

Respiratory depression is dose-dependent following exposure to opioids, leading to decreased respiratory rate and/or tidal volumes. The mechanism involves mu2 receptors that decrease sensitivity of the medulla respiratory center to hypercapnia. Opioids also suppress the hypoxic drive of ventilation. This combination is what eventually leads to apnea, although agonist–antagonists demonstrate a ceiling effect on respiratory depression.

Acute lung injury (ALI) from opioids has been reported since the 1880s and should be considered when hypoxia persists despite adequate respiration. Patients may develop hypoxia and pulmonary crackles within minutes or hours after regaining normal ventilation. There are several theories on the mechanism: (1) attempted inspiration against a closed glottis leading to negative intrathoracic pressure resulting in fluid shifting into to alveoli is a mechanical

mechanism. In addition, (2) similar to neurogenic pulmonary edema, a sympathetic vasoactive response from catecholamines on the myocardium produces cardiogenic pulmonary edema, and (3) some feel ALI is a result of hypoxia. No single mechanism can explain all cases of opioid-induced ALI at this time. In the past, naloxone was blamed as a cause of ALI, but ALI had been clearly documented prior to the development of naloxone and is seen in fatal overdoses that never receive this antidote. In addition, pulmonary edema may not be detectable until ventilation has been restored (6).

Another complication of opioid abuse is interstitial lung disease from the injection of insoluble binding agents in oral opioid tablets such as talc, cornstarch, or cellulose. The result is microscopic pulmonary emboli and inflammation progressing to interstitial fibrosis and pulmonary hypertension. Clinically, this presents as emphysema and chronic respiratory failure. Historically, the oral opioid most frequently cited in pulmonary talcosis is pentazocine, often used in conjunction with tripelennamine or methylphenidate known as Ts (for Talwin) and Blues (for the color of the other drug). It is also seen with methadone, meperidine, codeine, and oxycodone (7). Similarly, retinopathy may develop from the injection of oral medications (8).

Neurologic/CNS

All opioids can cause CNS depression, however other manifestations of opioid CNS toxicity include seizures in acute overdoes, most likely due to hypoxia. Seizures secondary to propoxyphene, tramadol, and meperidine toxicity are well described. Serotonin syndrome occurs when opioids with serotoninergic effects (meperidine, tramadol, and dextromethorphan) are used with monoamine oxidase inhibitors (MAOIs) or other serotonin agonists; however, similar symptoms occur with large doses of those opioids in the absence of other serotonergic drugs (Chapter 343, Serotonin Reuptake Inhibitors).

A severe, acute Parkinsonism has followed illicit use of a meperidine analog synthesized in a clandestine laboratory contaminated with 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). Affected individuals were known as “frozen addicts.”

Miosis

The mechanism of miosis caused by opioids is controversial. But, stimulation of mu receptors in the Edginger–Westphal nucleus of CN III by morphine does produce miosis. Miosis alone is not pathognomonic for opioid overdose. Overdose with numerous other substances can produce miosis and CNS depression including clonidine, organophosphates, phenothiazines, sedative–hypnotics, anticonvulsants, olanzapine, and ethanol. In addition, normally reactive or mydriatic pupils can be seen with meperidine, propoxyphene, tramadol, and Lomotil poisoning. Numerous polysubstance ingestions or abuse may confound pupillary findings with a variety of results.

Cardiovascular

Opioids can produce mild hypotension through nonspecific histamine release. This is often orthostatic and may not be evident in the supine position. Antihistamines are effective in blocking these effects. Opioids may also produce bradycardia secondary to decreased CNS stimulation.

Propoxyphene is known to have sodium channel–blocking properties similar to class 1 A antidysrhythmics which can produce QRS widening. This can lead to wide complex tachycardias and negative contractility. Methadone and its derivative LAAM may inhibit delayed potassium rectifier currents, increasing the QT interval and the subsequent risk for developing torsade de pointes. Prolonged QT syndrome and torsade de pointes appear to be dose-dependent and are more likely with high-dose methadone.

Gastrointestinal

Nausea and vomiting are common with therapeutic use and overdose. These effects are the product of dopamine-receptor agonism at the chemoreceptor trigger zone in the medulla. Antiemetics can be effective in controlling these symptoms. Constipation secondary to decreased GI motility is very common and is mediated by mu receptors within the GI tract.

Other clinical findings

Sensorineural hearing loss has been reported with opioid exposure usually after high doses and chronic use although it has followed acute overdose. Onset is sudden and rapidly progresses to bilateral hearing loss. Vestibular symptoms are usually, but not always, absent. Hearing loss may resolve with abstinence from opioids. Cochlear implants are usually successful.

Urinary retention due to increased sphincter tone may also develop. Other complications include pressure necrosis, compartment syndrome with rhabdomyolysis, hypoglycemia, and hypothermia in patients who have been comatose.

Tolerance and Withdrawal

Tolerance may be innate (genetically determined) or acquired. Acquired forms include *pharmacokinetic tolerance* from repeat exposure leading to changes in metabolism or distribution. *Pharmacodynamic tolerance* refers to physiologic adaptation such as changes in receptor density. *Learned tolerance* connotes a reduction of drug effects due to learned compensatory mechanisms such as the *conditioned tolerance* that develops when environmental cues are consistently paired with the administration of the drug. Some opiate overdoses experienced by drug addicts may occur if the drug is taken under new circumstances, tolerance is reduced, and the drug's effect enhanced. Numerous studies have demonstrated that altering the context of drug administration increases the lethality of many drugs, including opioids (9).

Although physical dependence and behavioral addiction is not fully understood, the mu receptor is involved in both processes and

the dopamine pathway is thought to be involved in dependence. Long-term use of opioids can lead to tolerance and withdrawal. Tolerance is most pronounced with the euphoric, analgesic, and sedative effects of opioids. Respiratory tolerance has also been reported in large therapeutic doses, up to 1,000 mg/hr of IV morphine without respiratory depression (10).

CNS excitation, tachypnea, mydriasis, nausea, vomiting, diarrhea, abdominal pain, myalgias, insomnia, piloerection, yawning, lacrimation, rhinorrhea are all symptoms of opioid withdrawal. These occur when stopping use or when an antagonist is delivered. Patients may present with significant fluid and/or electrolyte abnormalities from GI symptoms. Long-term opioid use is associated with decreased levels of endogenous opioids. If exogenous opioid administration is suddenly stopped, the inadequate amount of endogenous opioids fails to provide adequate inhibition to adrenergic pathways resulting in overactivation. Unlike benzodiazepine, barbiturate, and alcohol withdrawal, opioid withdrawal is generally not life-threatening but can cause seizures in neonates. It is important to note that opioid withdrawal does not cause altered mental status.

ED EVALUATION

The history should include the type of opioid, co-intoxicants, and the amount, time, intent, and route of exposure. The physical examination should focus on assessing the airway and the adequacy of ventilation. After the patient has been stabilized, it is important to look for fentanyl patches. The exam should include the all skin surfaces, including axillae, perineum, scrotum, and oropharynx. All patches should be removed and the area cleaned with soap and water to prevent any continued absorption. All major muscle groups should be palpated to evaluate the firmness, swelling, and tenderness that might reveal concerns for compartment syndrome. Patients should have cardiac and oxygen saturation or end-tidal CO_2 monitoring. Patients with altered mental status should have blood glucose testing and intravenous access established. Electrolytes,

creatine kinase (CK), and urine myoglobin should be checked if patients are combative, agitated, or convulsing. A chest radiograph and ECG should be obtained for unstable vital signs, hypoxia, or an abnormal cardiopulmonary examination. Acetaminophen and aspirin, found in combination with opioids in many medications, should be excluded. Urine drug screens (UDSs) detect some opioids, but will not detect propoxyphene, meperidine, methadone, fentanyl and derivatives, buprenorphine, hydromorphone, or naloxone. Hydrocodone and oxycodone may be detected in high concentrations. Heroin will be picked up as morphine, its metabolite. To specifically determine heroin use, 6-monoacetyl morphine (6-MAM), an intermediate metabolite between heroin and morphine, should be obtained. False positives for opiates on a UDS may include poppy seeds, dextromethorphan, chlorpromazine, diphenoxylate, ephedra, and ciprofloxacin. If action such as notification of child protective services or police is going to be based on the results of a UDS, the results should be confirmed by a second method such as gas chromatography/mass spectrometry. In contrast, a lack of response to adequate doses of opioid antagonists virtually excludes this diagnosis. Although most opioid-induced CNS depression will be reversed with lower doses of naloxone, some opioids such as propoxyphene may require doses as high as 10 mg. A positive response to naloxone is usually diagnostic, but clonidine and valproate (and rarely benzodiazepines, ethanol, and chlorpromazine) have been reported to occasionally respond.

KEY TESTING

- No testing for simple cases that respond to naloxone
- Electrolytes, BUN, creatinine, creatine kinase if comatose for a long time
- ECG
- Chest x-ray in suspected ALI

ED MANAGEMENT

Supplemental oxygen and assisted ventilation should be provided, as necessary. With the expeditious use of opioid antagonists and temporary ventilation via a bag-valve-mask, endotracheal intubation can often be avoided. Although the relationship between carbon dioxide and ALI is not clear, adequately ventilating and oxygenating the patient may help prevent a catecholamine surge that could contribute to the development of pulmonary edema (6).

Naloxone is a competitive opioid receptor antagonist that reverses opioids' clinical effects indicated primarily for the treatment of respiratory depression and may be effective for opioid-induced seizures. It can be diagnostic in patients with altered mental status of unknown etiology. The application of four-point restraints is recommended before naloxone administration, as the patient may become uncooperative and combative with reversal of opioid intoxication. Suction equipment should be set up in advance, because vomiting may occur after naloxone administration.

The onset of action of naloxone is typically less than 2 minutes when administered IV. In suspected addicts, a low initial dose of naloxone (0.04 mg IV) should be administered to avoid precipitating a severe withdrawal reaction. If there is no response, the dose should be increased every 1 to 2 minutes with escalating doses (0.5, 2, 4, 10 mg) or until respiratory depression is reversed and the patient awakens. Because some opioid overdoses (e.g., propoxyphene and methadone) are relatively resistant to naloxone, up to 15 mg may be administered. However, if the clinical findings are not reversed after the 10 mg dose, it is very unlikely that the cause is opioid toxicity. If the patient is not a suspected addict, 0.4 to 2 mg of naloxone can be given as the initial bolus. The effective dose of naloxone depends on the amount to which the patient has been exposed, the affinity of the opioid for the receptor, the patient's weight, and the ability of the opioid to enter the CNS. Of the other two opioid antagonists, naltrexone has a slightly longer half-life and is used for abstinence maintenance. Nalmefene has a much longer half-life and is more expensive. The use of longer-acting antagonists mandates a much longer observation period after

reversal of opioid effects. For that reason, naloxone is considered the best choice for use in the emergency setting.

If intravenous access cannot be obtained, naloxone may be administered via the intramuscular, intranasal, subcutaneous, or endotracheal route, but not orally because of extensive first-pass effect. The time to response after intramuscular administration is about the same as the time required to place an intravenous line and administer the drug. However, intramuscular administration decreases the risk of needlestick injury, especially in an uncooperative patient or with veins sclerosed from injection drug use.

Naloxone's duration of action is 20 to 90 minutes, which is a much shorter time than that of many opioids, especially after oral overdose and with diphenoxylate and methadone. Repeat doses or a continuous naloxone drip of two-thirds of the initial dose of naloxone needed to reverse respiratory depression, given every hour, should maintain arousal. It may be necessary to give one-half of the original dose as an additional bolus 15 to 20 minutes after initiation of the drip. Patients that improve after a single dose of naloxone should be observed 4 to 6 hours prior to considering discharge. Patients with exposure to extended release preparations, or recurrent respiratory depression, or needing naloxone infusion warrant admission to an ICU.

A partial response to naloxone requires a careful search for other accompanying illnesses, injury, or intoxicants. Endotracheal intubation is necessary in patients with hypercarbia, hypoxia, or an inability to protect their airway. Seizures should be treated with intravenous benzodiazepines (diazepam or lorazepam) or phenobarbital. Ongoing seizures suggest a cause other than pure opioid poisoning.

Within 1 hour of ingestion, activated charcoal should be considered. However, outside of this time frame it offers no benefit and is not without risk (aspiration, impairing airway visualization). Following ingestion of a fentanyl patch, whole bowel irrigation (WBI) with polyethylene glycol have been suggested to help with

elimination; however, studies of WBI have failed to show a difference in clinical outcome.

Hypotension is usually not a prominent feature of pure opioid overdose, and should be managed with crystalloid fluid and an aggressive search for another cause. Antihistamines may be helpful to block hypotension from histamine release. Propoxyphene may need vasopressors such as norepinephrine. Arrhythmias due to propoxyphene are similar to those of the tricyclic antidepressants and may require sodium bicarbonate therapy (see Chapter 339). Naloxone will not reverse propoxyphene cardiotoxicity. Although naloxone only partially inhibits tramadol-mediated analgesia, it reverses respiratory depression and coma due to this agent. Magnesium with potassium replacement may be required for methadone-poisoning, especially a prolonged QT_c or torsade de pointes.

If hypoxia persists following naloxone, this may be a sign of ALI. Fortunately, most cases only require supportive care, but some patients may require positive pressure ventilation or orotracheal intubation for severe hypoxia; most cases resolve within 24 hours. These patients are typically not volume overloaded, therefore diuretics do not play a role in the treatment. Rhabdomyolysis should be treated aggressively with fluid resuscitation to help prevent renal injury. Antiemetics can be effective in controlling nausea and vomiting. If compartment syndrome is suspected, immediate consultation for fasciotomy should be obtained.

CRITICAL INTERVENTIONS

- Administer naloxone to patients with altered mental status and respiratory depression.
- Begin with small doses of naloxone in opioid addicts with unintentional poisoning to avoid withdrawal.
- Give large doses of naloxone to those with intentional overdose and to children with accidental ingestions.
- Admit all patients who require naloxone after oral overdose and all children with possible opioid ingestions.

DISPOSITION

Careful observation is required for any patient requiring naloxone. Patients with intravenous overdose can be observed for 6 hours for evidence of relapse or the development of noncardiac pulmonary edema. Complications, if they develop, are usually evident soon after presentation. In contrast, patients requiring naloxone after an oral overdose should be admitted to an intensive care unit with cardiac and respiratory monitoring (and suicide precautions, as needed). They should not be discharged until they are symptom-free (off naloxone) for 12 hours. Adults who are or become asymptomatic for 6 hours after an oral overdose may be discharged. Children, especially those under age of 3, should be admitted for 12 to 24 hours, even if ingestion cannot be confirmed. Psychiatric or social work follow-up must be arranged for all intentional or pediatric poisonings. Asymptomatic patients who have been treated with narcotic antagonists should be monitored.

The appropriate disposal of transdermal fentanyl patches is an important matter. Historically, practices were to throw them in the trash or discard them in sharp disposal containers. However, secondary to residual fentanyl in a patch after delivery, witnessed drug wastage is now recommended. For ED disposal, the recommendation is drug wastage requiring co-signatures after cutting up the patch and flushing it down the toilet. For outpatient use, an exchange program of used patches for new patches may be helpful.

Common Pitfalls

- Failure to consider opioid overdose in patients who present with altered mental status, including seizures or combativeness, and CNS depression.
- Failure to apply restraints, thereby risking injury to staff, before giving naloxone to suspected addicts.
- Failure to evaluate for pulmonary complications, aspiration, and concomitant traumatic and medical illness.

- Failure to examine thoroughly for medication patches (e.g., fentanyl).

CHAPTER 306

Complications of Injection Drug Use

James A. Feldman and Lauren M. Nentwich

Although precise data are not available, the Centers for Disease Control and Prevention (CDC) estimated in 2002 that approximately 1.2 million people in the United States actively used nonprescribed drugs by intravenous, subcutaneous, and other routes of injection and in 2008 approximately 4 million had self-injected drugs at least once (1). Injection drug use (IDU) brings with it the risk of complications directly related to the local or systemic effects of the substances injected, the use of nonsterile methods of injection, and other aspects of injection practices as well as the risk of death from overdose (Table 306.1). The lifestyle associated with drug use also increases the risk of trauma and numerous infections including HIV, hepatitis, tuberculosis, and sexually transmitted diseases.

TABLE 306.1
Medical Complications of Injection Drug Use by Organ System

- Cutaneous
  - Needle foreign body
  - Abscess
  - Necrotizing fasciitis
  - Gas gangrene
  - Cellulitis
- Vascular
  - Septic phlebitis
  - Thrombophlebitis
  - Pseudoaneurysm
  - Infected hematoma
  - Intra-arterial injection
- Musculoskeletal
  - Vertebral osteomyelitis
  - Septic arthritis
  - Compartment syndrome
  - Pyomyositis
- Pulmonary
  - Pneumothorax
  - Hemothorax
  - Talcosis
  - Septic pulmonary embolus
  - Pneumonia
- Neurologic
  - Peripheral nervous system
    - Puncture injuries
    - Compression injuries
    - Plexitis/plexopathy
  - Central nervous system
    - Infections
    - Meningitis
    - Abscesses: cerebral, epidural, spinal
    - Mycotic aneurysm
    - Transient ischemic attacks
    - Mucormycosis
    - Stroke
- Internal organs
  - Heart
    - Endocarditis
    - Myocardial infarction, ischemia
  - Liver
    - Hepatitis
    - Spleen
    - Abscess
  - Kidney
    - Nephrotic syndrome
    - Glomerulonephritis
    - Abscess
    - Infarct
  - Intestine
    - Mesenteric ischemia, infarction
- General, other
  - Cotton fever
  - Septicemia
  - HIV infection
  - Tetanus
  - Wound botulism
  - Endophthalmitis
  - Amyloidosis
  - Malaria

Complications from unsafe injection methods are the most common reason IDU patients present to the emergency department (ED). Soft tissue infections such as abscesses and cellulitis often occur in IDU patients at the site of injection. IDU has been identified as an important risk factor for community acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA) especially of the USA 300 clonal group and is the predominant cause of purulent soft tissue infections (2). Observational studies have reported that IDU is associated with an increase in nasal carriage and wound colonization with CA-MRSA as compared to healthy or other control populations and cohort studies have demonstrated a significant increase in the prevalence of MRSA among those who use injection drugs over time (3,4). In addition to *S. aureus* and *Streptococci,* infections with gram-negative bacteria or oral anaerobes are also observed in IDU patients, related to nonsterile methods of preparation of the drugs.

Uncommon medical diseases, including wound botulism and tetanus, continue to be reported among patients using injection drugs. In 2005, all 28 reported cases of wound botulism in the United States were associated with IDU. Injection drug users are also at risk for more serious deep soft tissue infections, including necrotizing fasciitis (see Chapter 180), myositis, and pyomyositis. Broken needles at the site of intravenous injection are usually an incidental finding noted on radiograph. Such retained needle fragments rarely embolize centrally. However, serious complications such as pericarditis with pericardial effusion secondary to central migration have been reported.

Vascular complications related to IDU include unintentional intra-arterial injection, with resultant vasospasm or thrombosis and limb ischemia; venous and arterial pseudoaneurysm formation; development of an infected hematoma; and venous thrombosis and septic thrombophlebitis. IDU is a major risk factor for deep vein thrombosis, especially among those who have injected in the femoral veins.

Mycotic aneurysms involving central arteries such as the hepatic, mesenteric, cerebral, and pulmonary arteries and large vessel

occlusive emboli may occur in the context of endocarditis (see Chapter 88). Mycotic aneurysms involving the brachial, subclavian, axillary, and femoral arteries may develop after local injections. The bacteriology of both arterial and venous mycotic aneurysm is polymicrobial in up to 40% of cases. *S. aureus,* frequently β-lactam–resistant, is often cultured from the wound or blood. Anaerobic organisms have been reported in up to 20% of some series.

Injection into the supraclavicular fossa to access the jugular, subclavian, or brachiocephalic veins, known as "pocket shooting," often leads to pneumothorax, hemothorax, hydropneumothorax, or pyopneumothorax. In prior studies, moderate to large pneumothoraces and tension pneumothorax have been common findings.

Injection of solubilized tablets and capsules can lead to pulmonary dysfunction from injected particulate matter that deposit in the lung. Tablets are usually crushed, dissolved in water or other liquid, sometimes heated, and injected directly or through cotton filters. Talc fillers in tablets and other foreign materials induce granulomas in and around the arterioles and capillaries of the lung and deposit in retinal vessels; this condition is referred to as "talcosis." Both restrictive and obstructive pulmonary dysfunction can be seen along with pulmonary hypertension and cor pulmonale. Autopsy studies have suggested that this disorder, although confirmed histologically, is often not clinically recognized (5).

Osteomyelitis and septic arthritis secondary to IDU may result from direct contamination or hematogenous spread. Hematogenous pyogenic spinal infections from IDU include spondylodiscitis, discitis, vertebral osteomyelitis, and epidural abscess. Vertebral osteomyelitis is the most common form of skeletal infection in IDU patients, especially involving cervical sites compared to the lumbar and thoracic spine, which are more common in those who do not use injection drugs (6). Patients with osteomyelitis are more likely to have polymicrobial infections, infections due to gram-negative organisms, and anaerobic infections compared to those with septic arthritis (7).

The axial fibrocartilaginous joints including the sacroiliac, sternoclavicular, costochondral, hip, and pubic symphysis synchondroses are the most frequent sites of septic arthritis in IDU patients, although other joints, including the knees, hips, and shoulders, may be involved. *Pseudomonas aeruginosa* and *Serratia marcescens* often cause osteoarticular infections, but *S. aureus* is the most likely organism associated with IDU. *Eikenella corrodens* associated with "needle licking" causes septic arthritis in a subgroup of patient with IDU.

IDU patients are at increased risk of central nervous system (CNS) infections, including fungal and bacterial meningitis, cerebritis, and spinal epidural, and brain abscesses. Indolent CNS aspergillosis, cerebral mucormycosis, and anterior spinal artery syndrome with resultant paraplegia have been reported. A syndrome of cerebral mucormycosis is well described in IDU patients who are seronegative for the human immunodeficiency virus (HIV). Fungal endophthalmitis, caused by such organisms as Aspergillus and Fusarium, have been described in patients with IDU as the only identified risk factor for these rare infections. Peripheral nerve injuries may result from needle-induced trauma, extrinsic compression, and direct toxic or hypersensitivity reactions to injected materials.

Systemic infections may result from exposure to skin contaminants, contaminated apparatus, contaminated injection mixture, and blood-borne pathogens transmitted by the practice of needle sharing. Approximately 10% of new cases of acquired immunodeficiency syndrome (AIDS), and 50% of new hepatitis C cases are associated with IDU. In addition, HIV-infected patients on antiretroviral therapy who are active IDUs have increased morbidity and mortality compared to their non-IDU counterparts despite equal access to antiretroviral therapy. Infection with the HTLV virus (types I and II) is associated with IDU (8).

Hepatitis GB virus type C, an important cause of fulminant non–A-E hepatitis, is also more common in IDU patients. A number of uncommon infections have also been described, including disseminated candidiasis attributed to the use of lemon juice in the

preparation of brown heroin for injection, malaria (both falciparum and vivax), endophthalmitis, and tick-borne relapsing fever.

CLINICAL PRESENTATION

Patients with superficial abscesses often have localized pain, redness, and swelling at a previous injection site. Fever, cellulitis, and systemic complaints may also be present. Potential infection with MRSA should be presumed in all patients presenting with abscesses purulent cellulitis.

Tetanus presents as increased muscle tone, spasm, or trismus. Patients with wound botulism usually present with neurologic complaints such as cranial palsies or descending symmetric paralysis. Atypical signs, including asymmetric or unilateral cranial nerve weakness and peripheral motor weakness, may be present. Atypical presentations and false-positive edrophonium tests have caused patients to be misdiagnosed with Eaton–Lambert syndrome or myasthenia gravis, resulting in prolonged delays in appropriate therapy (9).

Deep soft tissue infections can have a subtle initial presentation but can rapidly progress to limb- and life-threatening illness. Myositis and pyomyositis may present initially with only mild erythema of the overlying skin but rapidly develop pain, significant edema, and crepitus. Sometimes a brown discoloration of the skin or purplish blebs develop. When the infection has progressed enough to cause marked cutaneous changes, the patient will frequently develop septic shock.

Broken needle fragments at injection sites may be asymptomatic or cause localized pain, as a result of the needle itself or of infectious complications. Patients may present with concerns about the risks of a retained needle fragment. They may also be unaware of its presence or fail to mention it unless asked.

Inadvertent intra-arterial injection causes immediate severe pain, hyperemia, numbness, weakness, distal swelling, cyanosis, and motor deficit and, often, sensory abnormalities. Distal ischemia may progress to gangrene, myonecrosis, and associated complications.

Injecting crushed oral medications into the lower extremity appears to be associated with more severe complications.

Venous pseudoaneurysms are most commonly noted in the groin and may present bilaterally. Pain, swelling, and purulent drainage may be noted. Some patients may appear clinically septic, with minimal localized complaints. In these patients, either pulmonary complaints or symptoms referable to sites of metastatic septic involvement may be more prominent.

Any mass over a vascular structure may actually be a pseudoaneurysm and should be approached with caution. Arterial mycotic aneurysms usually present as an indurated mass with local pain, and swelling. The mass may not be pulsatile, but a bruit is often heard over the swelling. Fever and leukocytosis are common, but bleeding, although occasionally massive, is usually intermittent, minor, or absent. Claudication, paresthesias, or compression neuropathy can occur. Signs and symptoms of distal embolic phenomenon, including cutaneous purpura, may be present and may precede systemic manifestations.

IDU patients with infective endocarditis usually have fever, but a new heart murmur, Roth spots, Osler nodes, Janeway lesions, splinter hemorrhages, or embolic phenomena are rare. The history and physical examination have a poor sensitivity and specificity for detecting infective endocarditis. The mortality rate in patients with IDU, HIV infection, and endocarditis is associated with the degree of immunosuppression as reflected by CD4 counts.

Patients with pneumothorax typically present with a history of recent neck injection, dyspnea, and pleuritic chest pain. Particulate-induced pulmonary dysfunction frequently presents as progressive dyspnea. Chest radiography can show a micronodular pattern which progress over time to show large homogenous opacities, usually in the perihilar regions and upper lobes. Chest computed tomography (CT) scans have demonstrated fine micronodular changes, perihilar conglomerate masses, ground glass attenuation, and emphysema, especially of the lower lobes, among patients who inject solubilized oral medications. Retinoscopy by an ophthalmologist can identify talc deposits (small, whitish, glistening dots) and may have a higher

diagnostic yield than either routine chest x-ray or pulmonary function tests.

Skeletal infections often present as localized pain and tenderness. IDU patients commonly develop septic arthritis and osteomyelitis at sites rarely seen in the general population, including the sternum, sacroiliac joints, and pubic symphysis. Almost 20% of patients with vertebral osteomyelitis related to IDU have had pain for more than 3 months at the time of diagnosis. Fever is usually absent or low grade. Neurologic signs and symptoms occur infrequently (<15%) and are usually transient. Patients with septic arthritis associated with IDU are similar in presentation to other patients with septic arthritis, except for the prominence of fibrocartilaginous joint involvement. Local signs of inflammation and fever, leukocytosis, and elevated erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are usually noted. Asymptomatic HIV infection has been reported prevalent among patients with septic arthritis.

A patient with fungal endophthalmitis usually presents with decreased vision, photophobia, and ocular pain, which develop slowly. The infection may occur in one or both eyes. White vitreal exudates may be seen on funduscopic examination. Bacterial endophthalmitis has a similar but more rapidly progressing presentation.

Patients with cerebral mucormycosis usually have headache, fever, and rapidly developing cranial nerve and motor deficits. Basal ganglia lesions on CT scan should suggest this diagnosis. Cotton fever may cause dyspnea, palpitations, headache, and rigors.

Patients who inject drugs are also at risk for systemic drug or drug contaminant toxicity (see Chapters 305, 310, 345, and 348), withdrawal syndromes (see Chapter 351), and CNS infections (see Chapter 278).

DIFFERENTIAL DIAGNOSIS

The most important requirement for developing an appropriate differential diagnosis is obtaining the history of IDU. Because patients often do not fit the stereotypes of end-stage IVDU, the

physician may miss this possibility. It may be necessary to consider the possibility of IDU, even if denied by the patient. In such cases, a urine screening test for drugs of abuse may be helpful.

Unless the history of IDU is routinely obtained or considered, conditions such as vertebral osteomyelitis and epidural abscess may not be considered in the differential diagnosis of complaints such as back pain. Consider botulism, endocarditis, or intracranial abscesses and mycotic aneurysms in the IDU patient presenting with stroke symptoms. What appears to be an abscess in an IDU may actually be a pseudoaneurysm, and a simple incision and drainage might have disastrous consequences. The IDU patient who develops a fever or flu-like symptoms is much more likely to have an infection requiring hospital admission than a non-IDU patient who presents with similar complaints. Infective endocarditis should be in the differential diagnosis of all IDU patients with fever, even if another source of fever is found. Studies from the 1980s and 1990s of patients with IDU with fever demonstrated that a small proportion of patients had major illnesses such as bacterial endocarditis that were not clinically apparent on initial evaluation. Although an acute but self-limited pyrogenic reaction induced by intravenous injection of foreign material from cotton balls used to filter injected solution is a common cause of fever, the history, physical examination, and routine laboratory testing cannot reliably differentiate “cotton fever” or other minor conditions from more serious causes of fever.

ED EVALUATION

The possibility of IDU, recent or remote, should be included in the standard “screening history.” A nonthreatening question such as, “Do you smoke cigarettes, or use alcohol or other drugs?” should be routinely asked of all patients. Depending on the clinical concern, it may be appropriate to ask patients about more specific questions about drug use including drug injected, amount, needle sharing, skin preparation (alcohol wipes), and whether they have a history of hepatitis, endocarditis, HIV, pain at injection sites, recent fever, and nonprescribed antibiotic self-treatment. Because many IDU patients

will not reveal their drug use, track marks or a positive urine toxicology screen may be the only clue to the diagnosis.

The physical examination of a patient with recognized IDU should include a careful review of vital signs, particularly an accurate temperature. Examination of the skin for signs of endocarditis, jaundice, infection at injection sites, and markers of HIV infection, such as oral thrush, should be performed in addition to a complaint-oriented examination. Evidence of opiate withdrawal, such as diaphoresis, lacrimation, yawning, pupillary dilation, and piloerection, should also be sought.

Routine laboratory tests are of limited use. Drug screens provide little information that will affect decisions, except possibly to suggest drug use when it is denied. Although the complete blood count and markers of inflammation (ESR, CRP) lack sufficient sensitivity and specificity to guide disposition decisions, if infection is suspected or diagnosed, a very high or low white blood cell count might prompt admission, even for a simple abscess. Point of care HIV testing that is increasingly available in EDs and can aid triage, treatment, and referral decisions.

Ultrasonography may identify occult abscesses that require drainage that otherwise would be missed on physical examination alone. Cutaneous abscesses with associated systemic complaints should be cultured. A radiograph or ultrasound should be considered in patients with cutaneous complaints of pain and tenderness at injection sites to exclude retained needle foreign bodies and to identify gas-forming infections. Surgical consultation should be considered for abscesses that could involve deeper tissue based upon their location or appearance. Deltoid abscesses have increased potential for deeper and more serious infections in IDU patients and are five times more likely to be drained and explored in the operating room compared to abscesses in other locations (10).

Suspected deep soft tissue infections such as myositis, pyomyositis, or necrotizing fasciitis can be evaluated with magnetic resonance imaging (MRI). However, given the rapid progression of these conditions, MRI should not delay surgical exploration for a definitive diagnosis in cases when there is high clinical suspicion.

Ultrasound may identify a perivascular abscess and color flow Doppler can readily identify nonvisceral mycotic aneurysms. Other imaging modalities such as CT or MR angiography or arteriography may be necessary to confirm the diagnosis.

Patients with suspected endocarditis should have three sets of blood cultures, a chest radiograph, and cardiac ultrasonography. A point of care transthoracic ultrasound performed as part of the ED evaluation can identify vegetations or valvular complications in patients with suspected endocarditis (it is specific, but not sensitive). Pocket shooters and those with respiratory complaints should have a chest radiograph and measurement of oxygen saturation. When they become available, advances in rapid diagnostic methods such as real time polymerase chain reaction (PCR) tests to detect bacteremia may better identify which febrile patients to admit.

Patients with joint pain and effusion should have two sets of blood cultures and aspiration, Gram stain, and culture of affected joints. Septic synchondroses may be safely aspirated in the ED and should be evaluated similarly. Diagnostic criteria for prosthetic joints infection differ (see Chapter 150). Two sets of blood cultures and an MRI should be obtained for suspected vertebral osteomyelitis or epidural abscess. An elevated ESR and CRP are not specific for osteomyelitis or septic arthritis and have limited utility for risk stratification or as triage tools. Using a normal ESR and CRP to triage IDU patients with back or neck pain who are at risk for an epidural abscess has not been validated in well-designed prospective studies. MRI is the modality of choice for detection of vertebral osteomyelitis and can be diagnostic for infected joints involving the axial skeleton and pelvis in uncertain cases. An MRI can also be normal in the early stages of an epidural infection. Given that history, physical examination, and all other diagnostic testing lack significant sensitivity and specificity, an MRI should be considered on all IDU patients presenting with axial skeletal pain. Laboratory studies can supplement the clinical evaluation.

Patients with complaints that suggest a CNS process (headache, weakness, ataxia) require a detailed neurologic examination, CNS

imaging with CT scan or MRI, and a lumbar puncture to identify cerebrovascular complications of IDU use, opportunistic CNS infections, or malignancy (whether related or unrelated to HIV infection). Patients with complaints of visual loss should have a complete eye examination, usually dilation with indirect funduscopy. In patients with fever, three sets of blood cultures, chest radiograph, urinalysis, and urine culture should be obtained.

KEY TESTING

- Febrile IDU should have testing appropriate for targeted source of infection
- Skin/soft tissue—consider bedside ultrasound and x-ray
- Musculoskeletal complications (osteomyelitis, epidural abscess, pyomyositis)
  MRI, blood cultures, routine laboratory studies
- Fever without evident source such as bacteremia, endocarditis should have blood cultures, ESR, CRP, possible point of care transcutaneous cardiac ultrasound to evaluate for vegetations
- Suspected CNS infection
  - Neuroimaging (CT angiography, MR angiography) with suspected cerebral mycotic aneurysm, (bacterial, fungal)
- Wound tetanus, botulism: have no diagnostic tests in the ED; the diagnosis is clinical.
- HIV testing if available or not recently performed

ED MANAGEMENT

Patients with IDU-related infections should be given tetanus prophylaxis as indicated. Localized cutaneous abscesses without vascular involvement may be managed with routine incision and drainage or loop drainage. If there is a possibility of vascular involvement, ultrasound or, needle aspiration should be done prior to drainage. Patients with localized infections involving the neck, groin, or vascular structures and those with suspected deep soft tissue infections such as myositis or pyomyositis should be evaluated by a surgeon. Although antibiotics and hospitalization are

not routinely required for cutaneous abscesses that have been drained, patients with HIV infection, neutropenia, vascular involvement, deep space infections, or possible sepsis should be admitted and given parenteral antibiotics. Extensive extremity infections, especially those found in the deltoid area, should be explored in the operating room, as inadequate drainage may prolong hospitalization. Ultrasound-guided regional nerve blocks or procedural sedation may be required for large abscesses.

Small uncomplicated abscesses without significant overlying cellulitis require only incision and drainage or placement of a loop. The addition of antibiotics is not shown to improve cure rate or outcome. Antibiotic treatment is advised for patients with abscesses that are complicated, have significant overlying edema, or are associated with systemic effects. Antibiotic choice should be guided by local antibiotic resistance and susceptibility patterns. The increasing prevalence of MRSA should be considered when choosing empiric antibiotic therapy. For inpatient therapy, vancomycin (Vancomycin 15 mg/kg IV q12h) can be used. For oral therapy, use trimethoprim–sulfamethoxazole (160/800 mg PO q12h) or double dosage to treat MRSA or severe MRSA infection, doxycycline (100 mg PO q12h), clindamycin (Clindamycin 300 to 450 mg PO q6 to 8h), though in many areas MRSA resistance to clindamycin is greater than 50% or linezolid (600 mg PO q12h), though its high cost may preclude widespread use. An antipseudomonal regimen including an aminoglycoside (APAG) such as gentamicin (traditional dosing 1 to 2 mg/kg IV q8 to 24h with the frequency depending on renal function, and high dose 5 to 7 mg/kg IV q24h) combined with an agent such as ceftazidime (2 g IV q8h) or cefepime (1 to 2 g IV q12h) should also be given if enteric organisms or *Pseudomonas* has been identified as part of the local “IDU” flora. Patients with gas-forming or necrotizing infections require *immediate* operative intervention and combination broad-spectrum antibiotic therapy that may include clindamycin (600 to 900 mg IV q8h), high-dose penicillin G (3 to 4 mU IV q4h, or vancomycin to treat MRSA and an APAG, and consideration of such adjunctive therapy as intravenous immunoglobulin and hyperbaric oxygen therapy. Such antibiotics as

piperacillin/tazobactam EI (3.375 g IV q8h) or imipenem (1 g IV q6 to 8h) can also be considered. Infectious disease consultation may be considered to aid in antibiotic selection and adjunctive therapy for such complex soft tissue infections as necrotizing fasciitis or myonecrosis associated with *Clostridium* (see Chapter 180). Early administration of antitoxin is important in patients with wound botulism (9). On March 22, 2013, the FDA approved the first botulism antitoxin that can neutralize all seven known botulinum nerve toxin serotypes. Heptavalent antitoxin (toxins A through G) is available at the CDC (770−488−7100 (24/7)). Early infectious disease consultation should be considered.

When associated with infection or vascular injury, needle fragments require urgent removal. Patients who have retained needle foreign bodies but do not have these complications may be given appropriate discharge instructions and referral to a surgeon for elective removal. In general, emergency physicians should not attempt to remove fractured needle fragments. Even if they are palpable, finding them may be difficult, important neurovascular structures may be injured, and migration may occur despite the use of a proximal tourniquet.

Patients with signs and symptoms of intra-arterial injection require aggressive management because of the potential for limb ischemia. Treatment should include antibiotics and anticoagulation with heparin. Consultation with a general or vascular surgeon is essential. Measurement of extremity compartment pressures should also be considered. A variety of off-label treatments have been described in case reports, including IV dextran 40 (20 mL/hr) and dexamethasone (4 mg q6h) or the intra-arterial injection of a vasodilator such as papaverine (40 to 60 mg), phentolamine (2 mg), iloprost, a prostacyclin analogue, and intra-arterial thrombolysis. Given the potential morbidity, appropriate infectious disease consultation should be considered.

Patients with pseudoaneurysms require blood cultures, preoperative laboratory testing including blood typing, and consultation with a general or vascular surgeon for excision and possible distal revascularization. Hospitalization is usually

indicated. An endovascular approach can be considered for some mycotic aneurysms by some specialists. Hemorrhage control with direct pressure may be required. Local drainage should not be attempted in the ED, as life-threatening hemorrhage may result.

Many experts continue to recommend admitting *all* IDU patients with fever as ruling out endocarditis and bacteremia remains problematic in the ED. Although one clinical trial conducted in 1996 suggested that oral antibiotics might be an acceptable alternative to intravenous therapy when intravenous access is very difficult or high risk in febrile drug users with possible endocarditis (e.g., "rule out endocarditis") this approach has not been studied in patients with MRSA infection. Advances using ultrasound to successfully obtain peripheral intravenous access in patients with difficult access have the reduced the risk and necessity of placing central lines in patients who are admitted to exclude bacterial endocarditis. Pulmonary dysfunction from other causes is treated by supportive measures.

Vertebral osteomyelitis and septic arthritis should be treated with vancomycin and an APAG. Ultrasound-guided arthorcentesis has become a well-accepted procedure performed by emergency physicians. Consultation with an orthopedic surgeon should be obtained. Spinal epidural abscess should be managed with urgent surgical drainage and empiric antibiotic therapy with both vancomycin and a third- or fourth-generation cephalosporin such as cefepime or ceftazidime until culture results become available (11).

Emergency physicians can consider hyperbaric oxygen therapy for some complications of IDU. Hyperbaric therapy has been reported as an adjunct to limb-threatening vascular injection, necrotizing infections, and complicated wound management.

Patients with cotton fever require only supportive care. This illness usually resolves within 12 to 24 hours. However, given the possibility that a serious medical condition is the etiology of fever, inpatient observation is recommended until the patient is well and the results of blood cultures are known.

CRITICAL INTERVENTIONS

- Consult an appropriate specialist for IDU patients with complicated infections, deep soft tissue infections, symptomatic retained needle fragments, limb ischemia, or masses in the neck or groin, or with vertebral osteomyelitis, septic arthritis, or visual complaints.
- Consider admitting all IDU patients for IV antibiotics until endocarditis and bacteremia can be excluded.
- Consider IDU in patients with multiple unusual infections.

DISPOSITION

Patients with cutaneous abscesses who are otherwise asymptomatic and healthy may be discharged with appropriate instructions and referral for follow-up in 24 to 48 hours. Patients with retained needle foreign bodies can be referred for elective surgery on an outpatient basis unless there are signs of infection. The ability of a patient to comply with outpatient therapy and follow-up should be considered. Most patients with other infectious complications require admission. Concomitant HIV infection should lower the threshold for admission.

Patients should be educated about practices that have been shown to reduce the morbidity and mortality from IDU. They should be referred for substance abuse treatment and, if available, to needle exchange; hepatitis, influenza, and pneumococcal vaccination programs; and for HIV, hepatitis, and sexually transmitted disease screening. Innovative efforts have combined screening for substance use, motivational interviewing, and linkage to drug abuse treatment. Patients can be referred to acupuncture, detoxification, needle exchange programs, outpatient buprenorphine providers, and other resources. Patients who continue to use injection drugs benefit from education about prevention practices, such as antiseptic skin preparation prior to injection, the use of bleach for cleaning needles and syringes, and the use of condoms. Programs that combine medical care with public health services have reduced ED visits by 40%, surgical admissions by 43%, and operating room procedures by 71% (7).

Common Pitfalls

- Failure to ask about IDU in all patients, including adolescents and older adults.
- Failure to consider the possibility of undiagnosed HIV infection.
- Labeling patients with IDU as "drug seekers" or allowing a judgmental attitude to interfere with a careful medical evaluation.
- Failure to appreciate that IDU patients with back pain as a result of vertebral infection may provide a history of minor trauma and have a normal neurologic examination.
- Attributing fever in an IDU to a trivial illness or to cotton fever.
- Attempting to drain a soft tissue mass in proximity to a major blood vessel.
- Failure to consider the possibility of arterial injection, compartment syndrome, deep-space infection, or nerve injury in patients with limb complaints.
- Failure to appreciate that extensive abscesses cannot be adequately drained in the ED.

PART 4 • ANTICONVULSANTS AND SEDATIVE-HYPNOTICS

CHAPTER 307

Barbiturates

Samuel J. Stellpflug and Carson R. Harris

Barbiturates are central nervous system (CNS) depressants used as anxiolytics and hypnotics, for the induction of anesthesia, and as anticonvulsants. They act by enhancing γ-aminobutyric acid (GABA) inhibition in excitable tissues mainly in the CNS, but also to a lesser extent in skeletal muscle, smooth muscle, and heart. Barbiturates bind to the $GABA_A$ receptor complex, augment the chloride current and also increase the duration of channel opening, hyperpolarizing the cells and thereby inhibiting depolarization. This enhances the activity of GABA, potentially acting synergistically with other GABA-active agents. That being said, especially in high doses, barbiturates can stimulate $GABA_A$ receptors directly even in the absence of GABA. In addition, phenobarbital also decreases the paroxysmal firing of nerve cells by an unknown mechanism along with GABA stimulation. Barbiturates are divided into four distinct categories based on their duration of action: (1) ultrashort-acting, (2) short-acting, (3) intermediate-acting, and (4) long-acting barbiturates (Table 307.1).

TABLE 307.1
Barbiturate Kinetic Data

Drug	Usual Adult Dose (mg)	Onset (hr)	Peak (hr)	Duration (hr)	Half-Life (hr)	Percentage Protein Binding	Volume of Distribution (L/kg)
Ultrashort-Acting							
Thiopental	50–75	<0.1	<0.1	<0.5	3–11	72–86	1.4–6.7
Methohexital	50–120	<0.2	<0.2	<0.5	1–4	83	1–2.6
Short-Acting							
Pentobarbital	50–200	0.25	0.5–2	>3–4	15–50	45–70	0.5–1
Secobarbital	100–200	0.25	1–6	>3–4	19–34	45–70	1.5–1.9
Intermediate-Acting							
Amobarbital	65–200	<1	2	>4–6	10–40	59	0.9–1.4
Aprobarbital	40–160	<1	12	>4–6	14–34	20	—
Butabarbital	100–200	<1	0.5–1.5	>4–6	66–140	26	—
Butalbital	100–200	—	2	—	61	—	—
Long-Acting							
Mephobarbital	50–100	0.5–2	—	>6–12	10–70	40–60	2.6
Phenobarbital	100–320	<0.1	0.5–2	>6–12	80–120	20–50	0.5–0.9
Primidone	300–1,000	—	—	—	3.3–12	20–30	0.4–1

The ultrashort-acting barbiturates (thiopental, methohexitol) are highly lipophilic, rapidly entering the CNS, and thus their primary use is anesthesia induction. Overdose of this group of barbiturates is typically iatrogenic as these agents are available only as intravenous formulations.

Short-acting barbiturates (pentobarbital, secobarbital) were extensively prescribed in the 1960s and 1970s as sedative–hypnotics. In the late 1970s, nearly 70% of all suicides by drug ingestion involved barbiturates (1). Their use markedly declined over the subsequent decades with the introduction of newer and safer sedative–hypnotics and anticonvulsants. Short-acting barbiturates have a lower therapeutic margin than the benzodiazepines, more frequent development of tolerance, and a greater potential for abuse. Moreover, drug–drug interactions are numerous, with more than 150 drugs and herbal interactions.

Intermediate-acting barbiturates (amobarbital, aprobarbital, butabarbital, butalbital) are most commonly found in combination analgesic medications (Fiorinal, Fioricet, etc.) containing butalbital to treat tension–vascular headaches. Amobarbital and butabarbital have been replaced by benzodiazepines, and the use of sodium amobarbital as “truth serum” has allegedly long been abandoned.

Long-acting barbiturates (phenobarbital and primidone) are still used to treat epilepsy. They have lower lipid solubility than short-acting barbiturates, causing them to accumulate more slowly in tissue and to have peak effects that are delayed for several hours.

Onset of symptoms usually occurs within 1 to 2 hours, and the peak effect may occur more than 10 hours after ingestion (2).

Pharmacokinetic data are summarized in Table 307.1. Barbiturates are well absorbed from the intestinal tract, except for mephobarbital, which is about 50% absorbed. The onset of action varies from 10 to 60 minutes depending on the agent and formulation. Food in the stomach decreases the rate of absorption but not the total amount absorbed. In overdose, the onset and peak of symptoms may be delayed. Ultrashort-acting barbiturates are administered intravenously, with initial effect seen within 1 minute and duration of effect of 10 to 30 minutes. Short-acting barbiturates are almost entirely metabolized in the liver to inactive metabolites that are excreted in the urine as glucuronides. However, liver metabolism of barbital, phenobarbital, primidone, and phenylethylmalonamide is limited because of lower lipid–water partition coefficients; so urinary excretion accounts for 95%, 25% to 35%, 15% to 42%, and 95% of the elimination of these agents, respectively. Phenobarbital undergoes enterohepatic recirculation, which contributes to its long half-life.

Barbiturates induce cytochrome P450 isozymes, including CYP2C9, CYP2C19, CYP2C8, and CYP3A4, thus enhancing elimination of other drugs metabolized by these enzymes. Although phenobarbital is a strong inducer of cytochrome P450, it does not induce its own metabolism and appears to have a longer half-life with chronic use (2). Barbiturates also induce δ-aminolevulinic acid (ALA) synthetase, leading to increase production of δ-ALA, a precursor of porphobilinogen. This may precipitate attacks of acute intermittent porphyria and porphyria variegata in susceptible individuals; thus porphyria, although uncommon, is a contraindication to barbiturate use.

CLINICAL PRESENTATION

Significant ingestions are now rare but still life-threatening and typically present with depressed level of consciousness ranging from lethargy to deep coma. Patients may also have respiratory depression, which is responsible for most deaths. With the short and

intermediate-acting barbiturates, symptoms usually begin within 1 hour of ingestion, and peak effects are seen within 4 to 6 hours. Patients with chronic lung disease and sleep apnea are more susceptible to severe respiratory depression, even at therapeutic doses. Other clinical findings in overdose include hypothermia, sluggish pupillary light reflex, nystagmus, and diminished bowel sounds. Bullous skin lesions, occasionally referred to as “coma blisters,” may appear on shoulders, hands, buttocks, and knees, where the body weight has caused pressure ischemia to the skin. About 40% of patients with severe toxicity also develop aspiration pneumonia (3). Cardiovascular collapse may manifest with bradycardia or tachycardia, hypotension, and shock. Drug-induced venous dilatation with consequent pooling of blood and reduction in effective vascular volume can lead to shock. Prolonged coma increases the risk for hypothermia, venous thromboembolism, rhabdomyolysis, and acute tubular necrosis secondary to shock. The acid–base abnormality, especially in a severe overdose, is likely to be a mixed respiratory and metabolic acidosis from hypoventilation and lactate. Coingested ethanol, benzodiazepines, and barbiturates have synergistic effects, and there is increased risk even when lesser amounts are ingested. Withdrawal symptoms occur when the drug is discontinued after chronic use of barbiturates leads to tolerance. Tolerance can develop with prolonged use and abuse, leading to a progressive increase in doses needed to achieve the desired effect. The withdrawal state is similar to ethanol withdrawal.

Laboratory abnormalities include hypoglycemia, electrolyte disturbances, and alterations in acid–base and fluid balance. The creatine phosphokinase (CPK) may be elevated if the patient has been comatose and immobile for a prolonged period. A chest radiograph may show aspiration pneumonia or pulmonary edema. The electrocardiogram (ECG) is usually normal but in severe toxicity may show bradycardia or tachycardia. The electroencephalogram (EEG) shows diffuse slowing during barbiturate-induced coma.

The amount of drug required to produce toxic symptoms can vary significantly depending on patient tolerance (4). The therapeutic doses for common barbiturates are given in Table 307.1. For

nonaddicted patients, the toxic dose for short-acting barbiturates is about 3 to 6 g (5 to 8 mg/kg in pediatrics) and for phenobarbital is about 6 to 9 g (8 mg/kg in pediatrics). Patients with physical dependence on barbiturates may tolerate higher doses. Geriatric patients may be much more sensitive to drug effects and can present with significant findings at lower doses. This may be attributed to decreased enzyme activity in the elderly and the higher likelihood of drug interactions and comorbidities in this population (5).

DIFFERENTIAL DIAGNOSIS

Other sedative–hypnotic agents, opiates, or alcohol intoxication should be included in the differential. Similar presentations may be encountered with γ-hydroxybutyrate, clonidine, skeletal muscle relaxants, and imidazoline decongestants (e.g., oxymetazoline). An overdose of psychiatric medications such as cyclic antidepressants, trazodone, phenothiazines, and antipsychotics also cause sedation and respiratory depression. Carbon monoxide poisoning, head trauma, CNS infections, sepsis, hypoglycemia, electrolyte abnormalities, and hypothermia may present similarly to barbiturate overdose and must be considered.

ED EVALUATION

The initial history is not always obtainable or reliable but, when possible, one should attempt to identify the drug ingested, the approximate amount ingested, the time of ingestion, and the reason for the ingestion (i.e., accidental or intentional). The physical examination should focus on the vital signs, including rectal temperature and oxygen saturation, and the degree of CNS depression. Other findings on examination may point to unsuspected trauma or other conditions in the differential. Absence of bowel sounds suggests ileus; suprapubic percussion or bedside ultrasound may detect a distended bladder.

After initial stabilization, physical examination, bedside fingerstick glucose and basic metabolic panel (electrolytes, blood urea nitrogen, creatinine) should be ordered. Testing is generally not helpful in the diagnosis but can detect other condition and may help general

supportive care. These include breath or blood alcohol concentration, and an acetaminophen concentration should be considered, as with most ingestions, and especially since it is contained in some preparations of barbiturate combination products. A salicylate concentration, and an ECG are reasonable, however will not be diagnostic of barbiturate ingestion. A complete blood count is almost always quite unhelpful. A total CPK concentration is reasonable, especially if there is concern for prolonged patient down time. With signs of acid–base imbalance blood gas analysis (venous if patient is well perfused, arterial if the patient has hemodynamic compromise) can help in the analysis. Chest radiography may reveal normal findings, however pulmonary edema and signs of aspiration are common. As with other causes of altered mental status, head computed tomography and lumbar puncture for testing is sometimes necessary to rule out causes other than ingestion. In the case of prolonged ED stay time, EEG can be obtained in the nonresponsive patient, but should not be used to rule out barbiturate overdose, as the EEG can reflect brain death in this setting.

Barbiturate-specific testing does not impact decision making in the emergency department (ED). Clinical signs of barbiturate overdose should dictate management rather than relying on serum or urine concentrations. Rapid urine immunoassay testing (“drug screen”) for qualitative presence of barbiturates is relatively reliable for exposure (more reliable than other drug classes tested by urine immunoassays), but is not particularly helpful because the exposure could have been hours or days prior to arrival and may not have anything to do with the clinical presentation. There can be an argument for never ordering rapid urine immunoassay screens in the workup of overdoses. Blood concentrations are not available at many facilities, and plasma concentrations may not accurately reflect brain concentrations, as tissue solubility changes with fluctuation in pH. However, quantitative testing can be done with more advanced techniques on serum and urine with chromatography combined with mass spectrometry, and this should be considered in cases where child abuse, elder abuse, and drug-facilitated sexual assault are

concerns. This may also prove beneficial in cases of clinical brain death without another reasonable cause.

KEY TESTING

- There are no specific tests for typical cases.
- Qualitative barbiturates levels may be helpful to document in cases of child abuse, elder abuse, date rape, and falsely presumed brain death.

ED MANAGEMENT

The treatment of barbiturate toxicity is primarily supportive. Patients with depressed respirations and altered mental status require airway management and intubation to support breathing and protect the airway. Blood pressure should be supported initially with intravenous crystalloid, administering 10 to 20 mL/kg boluses barring preventive comorbidities, and with close monitoring of response. The core temperature should be checked and rewarming instituted if needed. Management decisions should be based on the patient's clinical condition rather than on blood drug levels.

For serious phenobarbital overdose, multidose activated charcoal (MDAC) leads to more rapid recovery and a significant reduction in elimination half-life (6,7). The usual dose is 1 g/kg, followed in 2 to 4 hours by 0.5 g/kg in aqueous solution and alternating for 24 hours. Sorbitol-based charcoal has fallen out of favor and aqueous-based charcoal should be used.

Barbiturates are weak acids, and theoretically increasing the urine pH increases the fraction of ionized drug in the urine and thus decreases the amount of nonionized drug available for passive tubular reabsorption. This is most well established for phenobarbital and not well for other barbiturates; urine alkalinization can increase the renal clearance of phenobarbital up to 10-fold and can shorten the half-life by one-half to two-thirds (8). The best evidence for urinary alkalinization even in the context of phenobarbital is inferior to MDAC. There are no data to support the use of urine alkalinization for overdose with short- and intermediate-acting barbiturates (8).

Urine alkalinization is contraindicated in patients with renal insufficiency and cerebral or pulmonary edema.

Hemodialysis may be used in life-threatening barbiturate overdose (9). Early notification of the nephrology service can expedite initiation of treatment. Both charcoal hemoperfusion and high-flux hemodialysis enhance the elimination of all barbiturates. High-efficiency hemodialysis with a high blood flow rate may be superior to hemoperfusion which is also difficult to accomplish and has more inherent complications than dialysis (10). As these procedures have some risk, their use should be reserved for patients with pulmonary edema, cerebral edema, or shock unresponsive to supportive measures.

CRITICAL INTERVENTIONS

- Provide appropriate airway management with supplemental oxygen.
- Treat hypotension with intravenous fluids, and vasopressors if necessary.
- Administer MDAC, especially for phenobarbital poisoning.
- Consider early hemodialysis for severe overdoses, especially phenobarbital ingestions.

DISPOSITION

Nephrology consultation should be obtained when hemodialysis is being considered. Awake patients who have ingested short-acting barbiturates and whose symptoms are mild and are not progressing may be observed for 4 to 6 hours and then evaluated for psychiatric admission or discharged. For patients who have ingested long-acting barbiturates, the observation period should be based on both barbiturate levels *and* clinical symptoms. If quantitative serum concentrations are available (as with phenobarbital), serial concentrations can be obtained and the patient observed until concentrations peak and are decreasing, although this should likely be done during inpatient stays rather than in the ED. Patients with abnormal vital signs or significant CNS depression should be

admitted to an intensive care unit. Patients who require intensive care or extracorporeal elimination may need to be transferred if necessary. Advanced life-support measures to stabilize the patient and activated charcoal given prior to transfer. Suicide evaluation is indicated for all suspected suicide attempts when the patient is alert enough to be interviewed.

Common Pitfalls

- Failure to check for hypoglycemia as a cause of altered mental status.
- Failure to protect the airway in a somnolent patient.
- Failure to repeat MDAC and failure to check bowel sounds.
- Failure to consider barbiturate withdrawal in patient with seizures.

CHAPTER 308

Benzodiazepines

Samuel J. Stellpflug and Carson R. Harris

There are many different benzodiazepines (BZDs) marketed in the United States (Table 308.1) and these are widely used as anxiolytics, muscle relaxants, and anticonvulsants. Although BZD abuse and overdose is very common, life-threatening toxicity and fatalities are comparatively rare (1). That being said, BZDs are used for panic disorder and anxiety, conditions that may increase the risk of overdose (2). In addition, BZDs increase the risk of falling, particularly in the elderly and other physically at risk populations.

TABLE 308.1
Benzodiazepines Dosage and Kinetics

Agent	Dosage Oral (Adult mg/d, Child mg/kg/24 hr)	Peak Plasma Concentration (hrs)	Half-Life (hrs)	Major Active Metabolites ($t_{1/2}$ hrs)	PB (%)	Vd L/kg
Alprazolam (Xanax)	0.75–4 (1) 0.25, 0.5, 1 tabs	0.7–1.6	6–26	Yes	68–80	0.7–1

IV, intravenous; PB, protein binding; Vd, volume distribution
[a]not a benzodiazepine chemically but an imidazopyridine, which is selective benzodiazepine-1 receptor agonist.
[b]Not abenzodiazepine but a pyrazolopyrimidine derivative which is a $GABA_A$ benzodiazepine receptor agonist
[c]Half-lives include active metabolites.
[d]Average dose in parentheses.
Note: Half-lives vary; some include the metabolites half-life.

BZDs potentiate the inhibitory action of GABA by enhancing channel flow after binding nonselectively at BZD receptor sites that contain the $GABA_A$ α_1 subunit (3). BZDs enhance chloride ion permeability, rendering postsynaptic sites less excitable. Several BZD receptor sites have been identified in the CNS that modulate anxiolytic, hypnotic, neuroleptic, and anticonvulsant properties (3).

Receptor antagonists, such as flumazenil, competitively inhibit BZD effects.

Gastrointestinal (GI) absorption is rapid and complete for most BZDs, but absorption by the intramuscular route can be erratic and delayed. After oral administration, the rate of GI absorption, rather than lipophilicity, determines the onset of action. Diazepam, alprazolam, and triazolam are the most rapidly absorbed oral agents; prazepam is the slowest. Peak concentrations occur in 1 to 3 hours; ethanol enhances absorption and may cause the peak concentration to occur closer to 1 hour. In general the BZDs are highly protein-bound (85% to 99%).

After a single dose the more lipophilic BZDs, such as diazepam and midazolam, have a shorter duration of CNS action than less lipid soluble BZDs, such as lorazepam and chlordiazepoxide. Increasing lipophilicity enhances drug distribution out of blood and brain into inactive peripheral storage sites (adipose tissue), but after multiple doses, lipophilicity prolongs elimination. BZDs are primarily eliminated through hepatic metabolism. The two principal pathways involve either hepatic microsomal oxidation (*N*-dealkylation or aliphatic hydroxylation) or glucuronide conjugation (eFig. 308.1). BZD are substrates for cytochrome P450 (CYP) 2C19 and CYP 3A4 hepatic enzymes. CYP 3A4 is inducible by a variety of drugs, including rifampin, phenobarbital, and phenytoin (4). Elimination half-life can be increased by microsomal enzyme inhibitors, especially with midazolam. Examples of inhibitors include clotrimazole, erythromycin, estrogens, isoniazid, and ketoconazole (4). The elimination half-life is prolonged in elderly men because of unknown mechanisms, in obese patients because of an increased volume of distribution (Vd) and in patients with hepatic dysfunction because of impaired metabolism. Pharmacokinetic parameters and duration of action are summarized in Table 308.1.

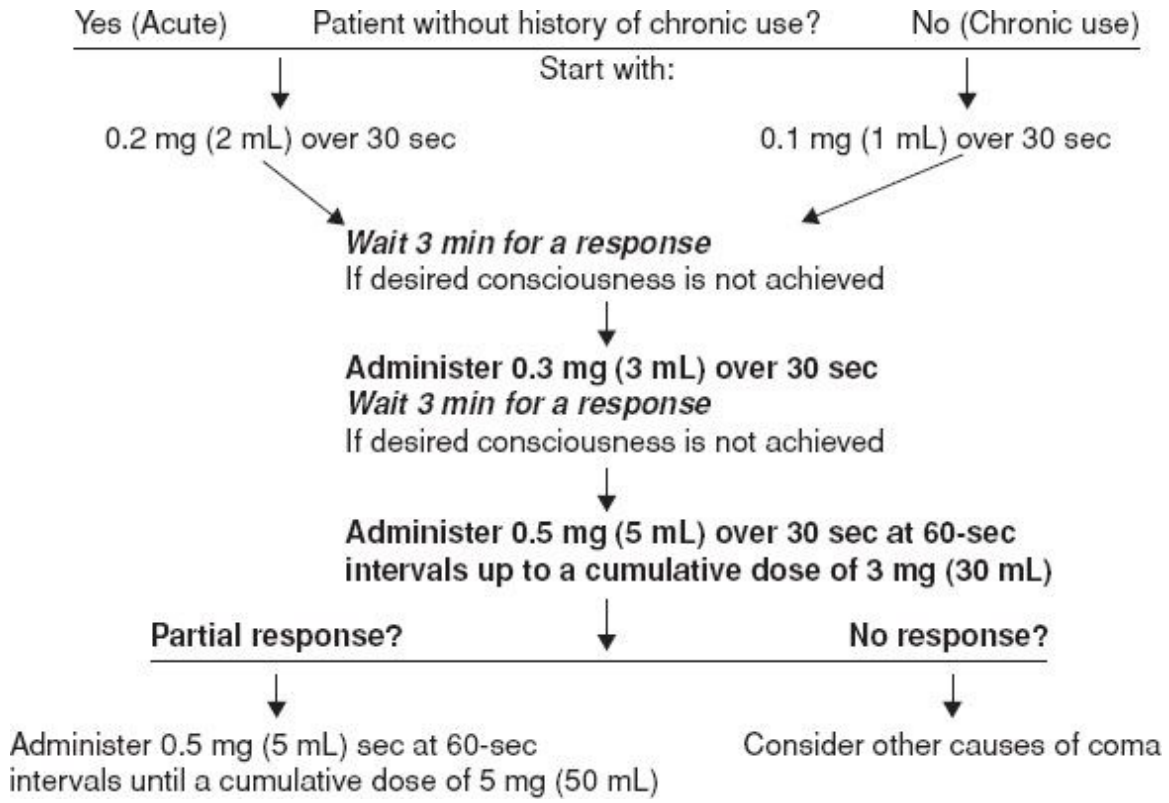

FIGURE 308.1 Flumazenil dosing for acute benzodiazepine exposure.

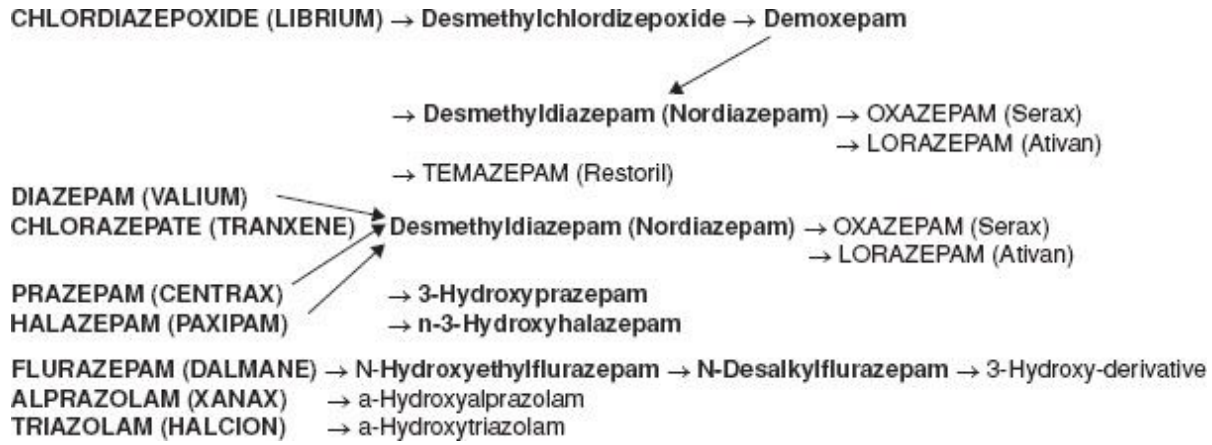

eFIGURE 308.1 Metabolism of benzodiazepines. Compounds in upper-case bold have active metabolites. Compounds in upper-case nonbold are active drugs without active metabolites. Compounds in lower-case bold are active metabolites. Compounds in lower-case nonbold are not clinically significant active metabolites.

A specific lethal dose for BZDs has not been established, as BZD-associated deaths most often occur in combination with other CNS depressants, such as ethanol. Rapid intravenous administration may result in apnea and hypotension. The propylene glycol vehicle used in parenteral BZD formulations may cause cardiovascular toxicity and may also lead to elevated anion gap metabolic acidosis.

Flunitrazepam (Rohypnol), known on the street as “roofies,” “Mexican valium,” “parachute,” and “roach 2,” is a BZD with a fast plasma peak sold by prescription in many countries. Flunitrazepam is sold illegally in the United States and abused as a “date rape” drug because of the antegrade amnesia it causes (3). The drug readily mixes with alcohol-containing beverages, although the manufacturer (Roche) has produced tablets that will break down into small particles and turn the beverage blue. It is touted as a remedy for the depression that often follows a stimulant high, hence the street name “parachute.” The onset of effects is within 0.5 to 2 hours, peak effect is <2 hours after oral ingestion, the duration of action is 8 hours or more after a 2-mg dose, and an elimination half-life is 20 to 30 hours (5). Flunitrazepam can be identified in urine from 4 to 30 days after ingestion, although routine drug screening immunoassays does not detect flunitrazepam. Your local laboratory may refer you to a national laboratories (such as NMS 800-522-6671) that can do forensic testing for “date rape” drugs. Quantitative drug levels are not useful or emergency department (ED) management but may confirm a diagnosis. Tolerance, drug coingestion, active metabolites, and distant tissue binding sites result in poor correlation between blood concentrations and clinical effects.

Newer “Z drugs” have replaced some BZD use because of their supposed lower side effects (6). Zolpidem (Ambien) is a non-BZD, imidazopyridine sedative–hypnotic drug. Imidazopyridines are thought to interact with the same GABA receptor/chloride channel complex as the BZDs by high affinity with the “central-type” BZD receptors. Zolpidem is approved only for short-term treatment of insomnia. It is rapidly absorbed from the GI tract, with a Vd of 0.54 L/Kg, 92.5% protein binding, and serum peak concentrations being reached in 1 to 2 hours. It is metabolized in the liver and has a half-

life of 2.5 hours, but is prolonged in the elderly (6). Like the BZDs, zolpidem overdose does not typically produce severe respiratory depression unless other agents are coingested. Although zolpidem produces some psychomotor and memory impairment over the first few hours after administration, it has few next-day effects (including effects on daytime well-being and morning coordination). Caution should be exercised in patients with obstructive sleep apnea. Adverse effects include headache, nausea, diarrhea, miosis, and next-day drowsiness. Confusion in the elderly can occur at doses of more than 20 mg. Zolpidem can cause withdrawal and tolerance (7).

Zaleplon (Sonata) is another non-BZD used for the short-term treatment of insomnia, which appears to cause less tolerance than triazolam, is less likely to potentiate the effects of ethanol, and is unlikely to produce amnestic effects. Zaleplon is rapidly absorbed and undergoes extensive presystemic metabolism. The compound has a plasma half-life of approximately 1 hour and is metabolized primarily via the aldehyde oxidase system. Because CYP3A4 may also contribute to metabolism (8), CYP inhibitors or inducers may affect zaleplon or the other drugs. The abuse potential of zaleplon (at doses above the therapeutic dose range) is similar to that seen with triazolam. Rebound insomnia and other withdrawal effects have not been demonstrated with zaleplon, and the drug is well tolerated in both young and elderly patients. These characteristics may be clinically advantageous for patients who should not receive BZDs (8) (see Chapter 310, Other Sedative-hypnotic Agents).

CLINICAL PRESENTATION

Manifestations of BZD poisoning include ataxia, lateral nystagmus, hypotonia, drowsiness, slurred speech, and coma (9). Even when BZDs are given in large doses, a deep coma causing cardiorespiratory depression and loss of deep tendon reflexes is rare. The ultrashort-acting agents and temazepam are important exceptions and are more dangerous.

Paradoxical excitement, including hallucinations, hostility, and seizures, have been reported with BZD overdose. Triazolam can produce delirium and psychosis. The elderly and very young children

are more susceptible to the CNS depressant action of BZDs. The toxic dose of flunitrazepam for a child is 0.1 mg/kg and is approximately 10 times as potent as diazepam. Most patients with acute BZD poisoning, however, recover without sequelae within 24 hours. Patients with pre-existing medical conditions such as hepatic disease may be more susceptible to toxicity.

A spectrum of affective disorders (psychosis, agitation, confusion, hallucinations, and delirium) and motor dysfunction (tremors, restlessness, myoclonic jerks, and seizures) may develop on withdrawal from diazepam when taken in daily doses of 60 to 300 mg. Seizures are rare and most commonly develop 7 to 8 days after withdrawal (range, 2 to 12 days). Withdrawal symptoms develop in an average of 3 to 4 days after discontinuation (range, 1 to 11 days), peak in 5 to 6 days, and resolve by 4 weeks, but minor symptoms may persist for months. Earlier onset and peak and shorter duration of withdrawal may be seen with shorter-acting agents (see Chapter 351).

DIFFERENTIAL DIAGNOSIS

The presence of deep coma, apnea or significant respiratory depression, hypotension, multiple organ involvement, or a prolonged time for recovery should prompt a search for coingestants (ethanol, other alcohols, other sedatives, narcotics, sympatholytics, cholinergics) or another cause (e.g., CNS lesions, trauma, infection, or metabolic disturbances). There is a long differential for decreased level of consciousness (see Chapter 11).

ED EVALUATION

The history should include the time and intent of all agents ingested and the amount and duration of chronic daily BZD documented, if possible. The physical examination should focus on vital signs, level of consciousness, cardiorespiratory function, and the ability of the patient to protect the airway.

Except for measurement of oxygen saturation, routine laboratory tests are not necessary in the verbally responsive patient. Unresponsive patients need appropriate testing for supportive care

such as a complete blood count, metabolic profiles, urinalysis, and blood gas analysis (venous if well perfused, arterial if hemodynamically compromised). Serum and urine testing for BZD is not helpful for clinical management but may confirm the presence of the drug to document in child abuse, elder abuse, sexual assault, and falsely presumed brain death. Most urine toxicology testing using immunoassay screening techniques have many false negatives since they detect only BZDs that are metabolized to desmethyldiazepam or oxazepam. In addition, most BZDs are not detected by thin-layer chromatography of the urine as a result of low drug concentrations.

KEY TESTING

- There is no special testing for BZD poisoning. Testing should be done as part of usual supportive care.
- Serum acetaminophen and other tests may rule out other exposures.

ED MANAGEMENT

Advanced life-support measures should be instituted as necessary. Massive overdoses of BZDs may have severe effects but most patients do well with simply good supportive care (9). Supportive therapy is usually all that is necessary when a BZD is the sole agent involved. Activated charcoal should be considered for patients within 1 hour of ingestion, although the evidence supporting this practice is lacking. Forced diuresis and hemodialysis are ineffective in enhancing BZD elimination because of high protein binding and volume of distribution. In uncomplicated cases, full recovery can be expected within 12 to 24 hours.

Flumazenil (Romazicon) is a specific competitive BZD receptor antagonist that reverses BZD-induced CNS depression. It also appears to reverse the sedative effects of zolpidem and endogenous BZD receptor agonists associated with hepatic encephalopathy. It does not antagonize other portions of the GABA receptor (e.g., barbiturate, ethanol, and general anesthetic binding sites) and does not change the bioavailability, plasma concentration, or elimination half-life of

BZDs. Most important, it may not reverse BZD-induced hypoventilation (10). Airway protection and mechanical ventilation are definitive treatment for respiratory distress or failure. In overdoses, flumazenil is best reserved for patients with pure, acute BZD overdose who are verbally unresponsive and have no history of seizures or long-term BZD use, as reversal may precipitate acute withdrawal. The use of flumazenil as a diagnostic and therapeutic tool in general patients with coma of uncertain etiology is not recommended.

In intravenous doses of 0.1 to 0.2 mg, flumazenil is partially antagonistic. In doses of 0.4 to 1 mg, onset of action and reversal of the CNS effects are evident within 1 to 2 minutes. An 80% response occurs within 3 minutes, and the peak effect is within 6 to 10 minutes. Duration and degree of reversal is related to the dose and the plasma concentration of BZD. Because flumazenil has a shorter duration of action than most BZDs, a 1-mg bolus usually lasts about 60 minutes but can last as long as 6 hours (10). The suggested treatment protocol for using flumazenil in patients with known or suspected BZD overdose is shown in Figure 308.1. It may be repeated in boluses of 0.1 mg or administered as an infusion of 0.1 to 0.5 mg/hr if necessary.

Patients who respond to flumazenil should be monitored for recurrence of sedation. Furthermore, because flumazenil may not reverse hypoventilation, patients who awaken may need to be reminded to breath (i.e., “take a deep breath”), and the adequacy of ventilation must be frequently reassessed. Emergence reactions after flumazenil administration (e.g., anxiety, agitation, confusion) can occur, particularly when flumazenil is given rapidly or in higher doses.

Flumazenil has no significant intrinsic pharmacologic activity. It has been reported to cause withdrawal and seizures in BZD-dependent patients, and it should be used in such patients with caution with lower than recommended doses and slower administration if the benefits are felt to outweigh the risks. Seizures have also been reported after flumazenil in patients intoxicated with cyclic antidepressants, cocaine, or isoniazid and in those with CNS

trauma. Flumazenil should not be given to patients taking BZDs as an anticonvulsant. A flumazenil-related dystonic reaction has also been reported. Naloxone, physostigmine, and stimulants such as aminophylline or theophylline are not indicated in the treatment of BZD poisoning.

Stopping the use of BZDs in any patient who has been maintained on these drugs longer than 6 weeks should be accomplished gradually over a minimum of 3 weeks and up to 2 to 3 months BZD withdrawal is managed with oral diazepam (10 to 60 mg) for several days, followed by tapering the dose by 10% daily, usually over several weeks with close follow-up.

CRITICAL INTERVENTIONS

- Protect the airway and provide ventilatory support with CNS depression.
- Titrate the dose of flumazenil to the desired effect, beginning with low doses and waiting at least 3 minutes for a response before administering incremental doses, particularly in patients with chronic BZD use.
- Most cases of BZD poisoning alone require only ED observation.

DISPOSITION

Patients with mild clinical toxicity (lethargic or asleep but who respond to verbal stimuli) can be observed in the ED until they recover. Psychiatric evaluation should be performed unless the exposure is accidental. Outpatient referral and follow-up are indicated for patients who have evidence of chronic abuse, dependence, or psychological problems such as depression and do not require inpatient therapy.

Patients who respond only to painful stimulation, regardless of whether flumazenil is given, probably require 12 or more hours of monitoring and treatment. If ED observation is not possible, these patients should be admitted to a closely monitored setting. Transfer is rare and indicated only if the initial facility lacks the equipment or personnel for caring for intubated patients.

Common Pitfalls

- Failure to consider coingestants or other causes of CNS dysfunction in patients with severe CNS depression.
- Failure to appreciate that most urine screening tests do not detect all BZDs.
- Failure to appreciate that flumazenil can precipitate seizures in patients with chronic BZD use, history of seizures, or the coingestion of drugs known to cause seizures.
- Failure to appreciate that recurrent toxicity can develop after flumazenil administration and that continued observation is necessary.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the contributions of Matthew W. Morgan, Thomas R. Carraccio, Howard C. Mofenson, and Robin B. McFee to this chapter in previous editions.

CHAPTER 309

Gamma Hydroxybutyrate

Stephen W. Smith

Gamma hydroxybutyrate (GHB) is a central nervous system (CNS) depressant and drug of abuse that is also present endogenously, at trace levels, in the brain and peripheral tissues. GHB occurs as a metabolite and precursor of the neuroinhibitory transmitter, gamma aminobutyric acid (GABA) and is proposed to be a neuromodulator. Initially used in France in 1960 as an anesthetic, popular use of GHB for purported anabolic effects began in the 1980s, followed by recreational use for euphoric, soporific, stimulant, and sexual effects. Use of GHB analogs (or precursors), gamma butyrolactone (GBL) and 1,4 butanediol (BD) began in the late 1990s in the form of GBL- and BD-containing "dietary supplements" (subsequently removed from the market). Both GBL and BD are industrial chemicals that, when ingested, are rapidly metabolized to GHB, with the same toxic and recreational effects (1). Unless specifically noted, references to GHB in this chapter refer to GHB and analogs.

Abuse of GHB, GBL, and BD continue. GHB is available through street supplies and is easily manufactured in home kitchens using "recipes" and ingredients readily available on the Internet. GBL and BD remain available as industrial chemicals and in cleaning products and solvents, including GBL-containing acetone-free nail polish removers. Product concentrations vary widely and are often unknown to users (2,3).

CLINICAL PRESENTATION

Acute GHB Toxicity

Although there is significant variability of GHB effects, the characteristic presentation of acute GHB toxicity is dose-related CNS depression, manifested as somnolence, lethargy, hypothermia, bradycardia, respiratory depression, coma, and death (1,2,4). The onset of coma may be rapid and abrupt, with Glasgow Coma Scale (GCS) scores of 3; symptoms typically resolve within several hours. Biphasic stimulant-sedative effects of GHB have been documented (5) and stimulant effects such as psychomotor agitation are commonly seen in acute toxicity cases, even in the absence of stimulant co-intoxicants. Agitation may occur before coma, in rapid alternation with somnolence or coma, in response to interventions such as intubation, as emergence delirium, or in the form of self-injurious behaviors (4,6). Urinary and fecal incontinence may occur, as well as nausea and vomiting, the incidence of which may be increased with alcohol co-ingestion. Myoclonus and/or seizure-like effects may occur and, far less frequently, true seizures. Ophthalmologic effects include blurred or distorted vision, loss of peripheral vision, disconjugate gaze, and nystagmus. Although controlled study has shown pupillary dilation with GHB administration, pupillary reactions in GHB toxicity cases are variable, likely due to effects of co-intoxicants. Rare cases of cardiac arrhythmias and atrial fibrillation have been reported. Additional effects include ataxia, sudden loss of muscle control, dizziness, confusion, headache, and amnesia (1,2,5,7).

The onset of GHB toxicity is rapid, typically 15 to 20 minutes post ingestion. The steep dose-effect of GHB results in characteristically abrupt onset and clearing of effects. Clinical effects typically peak approximately 30 to 60 minutes post ingestion. Duration of effects is dose-dependent, typically from 2 to 4 hours in nonintubated patients with no co-intoxicants (4,7).

GHB-associated fatalities have been reported, due to GHB intoxication and associated trauma, with and without co-intoxicants. In a series of 226 GHB-associated fatalities, 213 resulted from cardiopulmonary arrest and 13 resulted from motor vehicle collisions, drownings, and smoke inhalation; 34% occurred with no co-intoxicants (3).

The risks of GHB use and toxicity are increased by its steep dose response, abrupt onset, interindividual variability of effects, availability in diverse forms and concentrations, the common misperception that it is a "sleep it off" drug, and frequent use with co-intoxicants. Co-ingestion with alcohol or other CNS depressants may potentiate respiratory depressant effects (1–4).

GHB Dependence and Withdrawal

Chronic GHB use can result in the development of dependence and withdrawal. GHB-dependent individuals use multiple doses daily, some around-the-clock. Onset of withdrawal symptoms is rapid, generally within 1 to 6 hours of the last dose. GHB withdrawal presents with tremor, anxiety, agitation, diaphoresis, and insomnia. Symptoms may progress rapidly (within 24 hours) to hallucinations, delusions, and delirium (2,8,9).

In contrast with the severe autonomic disturbance documented for ethanol and sedative–hypnotic withdrawal, tachycardia and hypertension may be transient and mild, even in severe GHB withdrawal with profound delirium (8,9). Severe and refractory agitation increases the risk of hyperthermia, rhabdomyolysis, and DIC. Severe withdrawal may result in intensive care unit (ICU) stays of up to 15 days and result in death (8). Insomnia, depression, anxiety, and cognitive deficits may persist for weeks to months after detoxification and relapse is common. Because of frequent and chronic dosing, GHB-dependent users are also at risk of overdose and trauma resulting from motor vehicle collisions and falls. Co-dependency of GHB and other drugs is common (2,8,9).

GHB-Facilitated Sexual Assault

GHB is used to facilitate sexual assault due to its rapid onset, its disinhibitory and amnestic effects, its absence from routine hospital toxicology screens, and its rapid clearance from blood (4 to 6 hours) and urine (6 to 12 hours), leaving only CO_2 and H_2O as metabolites. Victims typically present late, beyond the window of detection for targeted testing; thus, false-negative testing is the rule. Amnesia

may or may not be associated with loss of consciousness, and victims may or may not remember the assault or assailant. GHB use should be suspected in patients presenting with unexplained lapses in memory of events, sudden onset of intoxication disproportionate to ethanol consumption or recorded ethanol level, missing or disheveled clothing, uncharacteristic behaviors, and symptoms consistent with GHB toxicity including sedation, agitation, and coma (10).

DIFFERENTIAL DIAGNOSIS

Important indicators of GHB intoxication are abrupt onset and clearing of effects and characteristic presentations of coma with psychomotor agitation. The differential diagnosis can be divided into two categories: (a) obtundation, stupor, and coma (see Chapter 11 for detailed discussion of the wide differential of altered mental status); and (b) psychomotor agitation which has many causes including ethanol, sympathomimetic drugs of abuse (PCP, amphetamines, methamphetamines), cocaine, or hallucinogens. Psychiatric disorders and withdrawal from ethanol or other sedative–hypnotic drugs must be considered.

The differential diagnosis of GHB withdrawal includes other withdrawal syndromes, head injury, CNS infection, anticholinergic or sympathomimetic poisoning, seizures, pheochromocytoma, serotonin syndrome, neuroleptic malignant syndrome, thyroid storm, and functional psychosis.

ED EVALUATION

Because GHB is not detected on routine hospital toxicology screens, the diagnosis of GHB toxicity must be made clinically. The ED history should focus on details of the onset and course of altered mental status, specifically: (a) rapid and abrupt onset of altered mental status and coma, particularly when known to be disproportionate to the amount of alcohol or drugs consumed; (b) periods of psychomotor agitation occurring prior to onset of coma, agitation in rapid alternation with somnolence or coma (2- to 3-

minute cycles), agitation in response to interventions such as intubation, emergence delirium after coma, and self-injurious behaviors; and (c) rapid and abrupt clearing of effects. Dance clubs, raves, parties, and bars are common venues for use of GHB and other "club drugs," alone or in combination. Physicians should also question patients regarding past medical and psychiatric history and regular medications. GHB withdrawal is also diagnosed by history; physicians should question patients regarding chronic use, time of last dose, and onset of withdrawal symptoms.

Physical examination should include assessment of vital signs, cardiopulmonary function, and neurologic status. Assessment and frequent monitoring of respiratory status (airway patency and protection, adequacy of ventilation) is of primary concern, particularly in coma. Pulse oximetry is recommended. Arterial blood gases may detect hypoventilation.

Testing is usually not helpful in GHB intoxication or withdrawal. Blood ethanol and drug screens and blood urea nitrogen (BUN), creatinine, electrolytes, fingerstick glucose, and urinalysis are usually unnecessary but may be helpful in specific circumstances.

With GHB withdrawal, electrolytes, BUN, Cr, glucose, complete blood count with differential, coagulation studies, transaminases and liver function tests, creatine phosphokinase (CPK), urine drug screen, and drug levels (i.e., anticonvulsants, antidepressants) may help to detect complications from ongoing GHB use.

GHB is not detected on routine hospital toxicology screening. Confirmation is by targeted analysis with gas chromatography/mass spectrometry, which requires approximately 1 week and thus does not help ED management. For forensic evidence in cases of suspected GHB-facilitated sexual assault, because of its rapid clearance, 100 mL of first-catch urine should be collected and refrigerated. If a blood specimen is necessary, 10 to 30 mL should be obtained in a gray top tube (with sodium fluoride and potassium oxalate) and refrigerated. Established chain of custody procedures should be followed.

KEY TESTING

- There is no confirmatory ED test for GHB.
- Testing should concentrate on detecting complications.
- Forensic testing relies on sending a first-catch urine sample with chain of custody.

ED MANAGEMENT

Management of acute GHB toxicity is supportive. Airway protection, adequate oxygenation, and prevention of aspiration are the goals. Frequent monitoring is necessary, and intubation and mechanical ventilation may be indicated. Sedation may be necessary for agitation. Because many patients recover rapidly and spontaneously, a conservative approach to intubation is appropriate; however, the low frequency of reported intubation complications must be weighed against the potentially lethal risk of respiratory depression. Rapid-sequence intubation using succinylcholine is recommended; otherwise, intubation attempts of an apparently comatose patient may trigger agitation. Bradycardia is typically asymptomatic, but the use of atropine may be necessary. The few reported cases of atrial fibrillation have resolved spontaneously.

Physical and/or chemical restraints may be needed for control of agitation. Benzodiazepines such as lorazepam (1 to 3 mg IV or IM) or butyrophenones such as droperidol (2.5 to 5 mg IV or IM) or haloperidol (5 to 10 mg IM) may be administered.

Though myoclonic movements have been well documented, seizures are rare. Although causality is not apparent, in the absence of definitive data, benzodiazepines such as lorazepam 2 to 4 mg IV or midazolam 2 to 4 mg IV can be employed for seizures. CPK levels, cardiac enzymes, and urine myoglobin may be indicated to monitor for rhabdomyolysis.

Gastric lavage and activated charcoal are not indicated, because of GHB's rapid absorption. There are no proven antidotes or reversal agents for acute GHB intoxication. Naloxone should be considered only in cases of suspected co-ingestion of opioids (7).

GHB withdrawal requires aggressive supportive care and is very similar to management of severe delirium tremens. Agitation and

delirium must be controlled and efforts made to prevent hyperthermia, rhabdomyolysis, renal failure, injury, and other complications. Long-acting sedatives such as diazepam (10 mg IV per dose, and titrated to restfulness) are recommended. Propofol may be used for intubated patients, starting with an IV infusion of 5 μg/kg/min (0.3 mg/kg/hr) for 5 to 10 minutes until sedation is achieved, and maintaining infusion rates of 5 to 50 μg/kg/min. Barbiturates such as pentobarbital (100- to 200-mg IV increments) or phenobarbital (250-mg IV increments), titrated for symptom control, may also be utilized (6). Close monitoring and continuous pulse oximetry are critical after administration of sedative agents described earlier, and intubation and mechanical ventilation are frequently necessary.

CRITICAL INTERVENTIONS

- For acute GHB toxicity:
  - Intubation and mechanical ventilation for airway protection
  - Treat agitation with benzodiazepines and/or antipsychotics such as butyrophenones (droperidol or haloperidol) or newer antipsychotics such as olanzapine
  - Monitor for rapid development of GHB withdrawal
  - Question for history of known or suspected GHB use
- For GHB withdrawal:
  - Adequate sedation
- For suspected GHB-facilitated sexual assault:
  - Symptomatic treatment and appropriate specimen collection in accordance with chain of custody procedures

DISPOSITION

The majority of cases of acute GHB toxicity resolve spontaneously without complications within 2 to 6 hours. After close observation, patients may often be discharged from the ED when clinically stable and mental status has fully normalized. For coma requiring intubation and mechanical ventilation, admission to the ICU may be necessary; however, as with patients managed in the ED, recovery in

the ICU may be rapid and abrupt, and patients may self-extubate. Complications such as aspiration or associated trauma may also necessitate ICU admission. Signs of GHB withdrawal can develop rapidly after the patient wakes up. This may begin in the ED or in the ICU in patients who have presented with acute toxicity. Counsel patients regarding the potentially lethal risks of GHB. For habitual users, referral for substance abuse counseling and treatment is critical.

Common Pitfalls

- Assuming that a negative toxicology screen rules out GHB; GHB is not included on standard hospital toxicology screens.
- Confusing the diagnosis of GHB intoxication with other drugs: Agitation resulting from GHB toxicity, in particular may be mistakenly attributed to stimulants such as methamphetamine, cocaine, PCP, etc.
- Missing GHB-facilitated sexual assault in patients presenting with altered mental status or unexplained memory loss.
- Failure to note early signs of GHB withdrawal after awakening from acute toxicity.

CHAPTER 310

Muscle Relaxants and Other Sedative–Hypnotic Agents

Benjamin S. Orozco and Samuel J. Stellpflug

Muscle relaxants refer to drugs used to mitigate muscular spasm through various mechanisms. Sedating medications have been used for muscular spasm and muscle relaxants are often sedating; consequently, there is substantial overlap in therapeutic and toxic effects between muscle relaxants and sedative hypnotics. Muscle relaxants used to treat muscle spasms and spasticity include baclofen, chlorzoxazone, cyclobenzaprine, dantrolene, metaxalone, carisoprodol, methocarbamol, orphenadrine, and tizanidine. The nonbarbiturate, nonbenzodiazepine sedative–hypnotic agents used for the relief of anxiety and as sleeping aids include buspirone, chloral hydrate, eszopiclone, meprobamate, ramelteon, zaleplon, zolpidem, and zopiclone. Ethchlorvynol, glutethimide, and methaqualone are no longer available in the United States. See elsewhere for a discussion of other sedative hypnotics such as barbiturates and benzodiazepines (Chapters 307 and 308, respectively) and sleep aids such as diphenhydramine or sodium oxybate (GHB) and related compounds (Chapters 344 and 309, respectively).

Most sedative–hypnotics and muscle relaxants are metabolized in the liver. Several undergo oxidation by cytochrome p450 enzymes, making drug interactions a concern. Pharmacokinetic data for these agents are summarized in Table 310.1. A list of important drug

metabolizing enzyme substrates is summarized in the content Table 310.2.

TABLE 310.2
Drug Metabolizing Enzymes

Drug	Cytochrome Substrate	Inducer/Inhibitor
Buspirone	CYP 3A4	
Eszopiclone	CYP 3A4 (major), 2E1 (minor)	
Carisoprodol	CYP 2C19	
Chloral hydrate	CYP 2E1	
Chlorzoxazone	CYP 2E1	
Cyclobenzaprine	CYP 1A2, 2D6, 3A3/4	
Orphenadrine	CYP2B6, 2D6, 3A3/4	CYP 2B6 inhibitor
Ramelteon	CYP 1A2 (major), 3A4/2C family (minor)	
Tizanidine	CYP 1A2	
Zaleplon	CYP 3A3/4 (minor)	
Zolpidem	CYP 3A3/4	

CLINICAL PRESENTATION

The majority of sedative hypnotic agents are well absorbed, and onset of effect occurs within 30 minutes to 1 hour after ingestion, sooner for zaleplon. Orphenadrine and cyclobenzaprine may have delayed onset of action, likely as a result of anticholinergic properties.

Grouping drugs with similar mechanisms or toxicities helps with a conceptual understanding of the poisonings though several agents have unique or unexpected toxicities. In overdose, central nervous system (CNS) depression with respiratory depression is expected, and this effect may be accentuated by co-ingesting alcohol or other CNS depressants. Respiratory failure and apnea are a potential with any sedating medication, but the older sedative–hypnotic agents (e.g., chloral hydrate, meprobamate, and carisoprodol) have a lower safety margin than benzodiazepines and newer nonbenzodiazepine sedative–hypnotic agents, such as buspirone, eszopiclone, ramelteon,

zaleplon, zolpidem, and zopiclone. Respiratory arrest due to one of these newer agents is uncommon without co-ingestants.

The sedative hypnotics and muscle relaxants with γ-aminobutyrate (GABA) potentiation will cause CNS and respiratory depression in overdose. This includes meprobamate, chloral hydrate, carisoprodol, zolpidem, zolpidem, zaleplon, zopiclone, eszopilcone, and baclofen. All of these agents can be abused and when used long term at high doses, there is risk of withdrawal complicated by seizures or a delirium tremens-like syndrome.

Meprobamate and chloral hydrate potentiate GABA activity and cause CNS depression. Meprobamate, a drug first used in the 1940s, has anxiolytic, anticonvulsant, and skeletal muscle relaxant properties. In addition, overdose of meprobamate may cause myocardial depression and hypotension. Prolonged toxicity may occur secondary to pharmacobezoar formation (1). Chloral hydrate is one of the oldest known hypnotics and is still used for procedural sedation in children. Chloral hydrate is metabolized by alcohol dehydrogenase to trichloroethanol, and a portion is subsequently oxidized to trichloroacetic acid. Toxicity results from the parent drug and metabolites. The half-life of its active metabolite, trichloroethanol, is 8 hours at therapeutic doses but may be prolonged to 12 to 35 hours after overdose. The combination of alcohol and chloral hydrate (“Mickey Finn”) is particularly potent; these agents not only have additive CNS depressant effects but also inhibit each other’s metabolism. In overdose chloral hydrate may present with coma, miosis, and hypotension. This presentation could be confused with tizanidine or similar agents discussed below. Chloral hydrate is also a gastrointestinal irritant and frequently causes nausea and vomiting. Hemorrhagic gastritis and gastric necrosis occur rarely. As a halogenated hydrocarbon, it can also cause hepatic injury, renal failure, and cardiotoxicity. It reduces myocardial contractility, shortens the refractory period, sensitizes the myocardium to circulating catecholamines, and precipitates dysrhythmias (see Chapter 331).

The nonbenzodiazepine sleep aids are short-acting drugs that potentiate the GABA chloride channel via the benzodiazepine

receptor complex (zolpidem, zaleplon) and possibly at other sites (zopiclone, eszopiclone). A review of eszopiclone, zolpidem, and zaleplon ingestions found drowsiness as the most common clinical effect. Tachycardia and slurred speech were noted in 5% to 10% with zolpidem and zaleplon. Agitation and irritability occurred in 5% of eszopiclone exposures. The patients who took zolpidem and zaleplon had mild CNS effects, including dizziness, slurred speech, and lethargy. Few patients had nausea, vomiting, or abdominal discomfort. Deep sedation is rare barring co-ingestant (2,3).

Baclofen, a muscle relaxant used for chronic spasticity, interacts with the GABA B type receptor may cause profound CNS depression with loss of cranial nerve reflexes. Moreover, it is utilized orally and/or in intrathecal pumps and may paradoxically cause refractory seizures in overdose and in withdrawal. Autonomic disturbances (e.g., bradycardia or tachycardia, hypotension, or hypertension) or dysrythmias occur less frequently. Pupillary response is inconsistent with mydriasis and miosis both reported. Serum concentrations do not correlate with toxicity. Elimination of baclofen is unpredictable after overdose where coma may be consistent with its 3- to 8-hour half-life or quite prolonged. In a series of adolescents with acute baclofen toxicity, mechanical ventilation was required for up to 60 hours after ingestion (4).

Cyclobenzaprine and orphenadrine have anticholinergic properties in overdose though muscle-relaxing effects are due to sedation. The anticholinergic effects may cause confusion, agitation, and hallucinations, which may also occur after therapeutic doses. These agents may precipitate seizures in overdose. Orphenadrine is structurally similar to diphenhydramine and may also cause QRS prolongation and ventricular tachycardia due to sodium channel blockade. Although cyclobenzaprine is structurally similar to amitriptyline, serious cardiovascular effects were not noted in a series of 209 isolated cyclobenzaprine ingestions. This may be due to less toxicity and lower dosage formulation of cyclobenzaprine in contrast to amitriptyline (5).

Tizanidine, a centrally acting α-2 adrenergic agonist similar to clonidine and guanfacine, may be used to treat tension headaches

and trigeminal neuralgia in addition to muscular spasticity. Overdose produces hypotension and relative bradycardia accompanied by miosis, which may be confused with opioid poisoning. Effects generally resolve in less than 24 hours.

Buspirone, a sedative–hypnotic, antianxiety agent, is a partial agonist at the serotonin 1A (5-HT1A) receptor. Its exact mechanism is not known, although it does not interact with the benzodiazepine–GABA receptor complex. Seizures have been described 36 hours after the ingestion of 420 mg of buspirone (6). Serotonin syndrome (see Chapter 343) may occur in patients concurrently taking buspirone and a selective serotonin reuptake inhibitor, trazodone, or St. John's wort.

Dantrolene, a skeletal muscle calcium channel antagonist, is used for malignant hyperthermia, neuroleptic malignant syndrome, and chronic spasticity, but chronic use can cause hepatotoxicity limiting widespread use. There are no published cases of dantrolene poisoning.

Ramelteon is a selective melatonin receptor agonist approved for the treatment of insomnia. It is metabolized in the liver to the major metabolite M-II, which is active and has weak affinity for the serotonin 5-HT_{2B} receptor. Possible serotonin syndrome was associated with ingestion of 30 8-mg ramelteon tablets in a woman on escitalopram (7), but no serious toxicity was observed by a poison center over 5 years ($N = 222$). Lethargy/drowsiness was by far the most common effect (5).

Many of the other muscle relaxants (carisoprodol, chlorzoxazone, ethchlorvyol, glutethimide, metaxalone, methaqualone, and methocarbamol) are muscle relaxants primarily via sedation and cause varying degrees of CNS depression in overdose. Coma may be prolonged in severe ethchlorvynol and glutethimide overdose. Glutethimide also has anticholinergic properties and may cause alternating periods of coma and agitation. Methaqualone commonly causes muscle hyperactivity, including hyperreflexia, twitching, and clonus, in addition to CNS depression. Hypotension and respiratory depression occur infrequently. Carisoprodol, which is metabolized to meprobamate, is the most abused of the muscle relaxants and has

been a Drug Enforcement Administration Schedule IV drug since 2012. Most of the sedative hypnotics including meprobamate are also Schedule IV. In overdose, carisoprodol may present with tremor, myoclonus, muscle rigidity and less often, tachycardia, and hypertension (8). Abrupt discontinuation may result in withdrawal.

DIFFERENTIAL DIAGNOSIS

Poisoning by alcohols, anticonvulsants, barbiturates, benzodiazepines, β-blockers, calcium channel blockers, centrally acting antihypertensives, cyclic antidepressants, opioids, and skeletal muscle relaxants can all cause similar signs and symptoms. Hypotension out of proportion to the degree of CNS depression suggests meprobamate, a cardiovascular agent, or a cyclic antidepressant. Cyclic coma suggests glutethimide, GHB ingestion or formation of a gastric pharmacobezoar. CNS infection and trauma, hypoglycemia, hypernatremia, hypercalcemia, and hypermagnesemia should also be considered. Ingestion of plants, mushrooms, and many different nonprescription and prescription medications can all cause anticholinergic symptoms.

ED EVALUATION

The history should include the time and amount of drug(s) ingested, the time and the nature of symptoms, and medical history, including the pattern and extent of muscle relaxant or sedative–hypnotic use. The physical examination focuses on vital signs, level of consciousness, and cardiopulmonary status.

Symptomatic patients may have baseline laboratory testing as needed for general care. Serum glucose concentration with decreased level of consciousness, electrolytes, blood urea nitrogen (BUN), creatinine, and an electrocardiogram may be useful. Chest radiography or blood gas measurements may be helpful if aspiration or pulmonary edema is suspected and markers of hepatotoxicity if a hepatotoxin has been ingested (chloral hydrate). Patients with deep coma, pressure sores, or seizures should be evaluated for rhabdomyolysis by serum creatine phosphokinase and urinalysis. Drugs-of-abuse immunoassays will not detect these agents, and will

likely be more misleading than helpful. For example, cyclobenzaprine may cause a false positive for tricyclic antidepressants. Comprehensive urine toxicology tests may confirm presence of some agents but does not guide emergency department management. Quantitative serum level testing is not clinically useful.

KEY TESTING

- Complete set of vitals and continuous waveform pulse oximetry
- Blood glucose if decreased conciousness
- EKG to evaluate intervals (QRS and QTc) prolongation
- Serum chemistries, BUN, creatinine in symptomatic patients

ED MANAGEMENT

Therapy involves stabilization and support of vital signs and early decontamination with activated charcoal if mental status permits. Most patients recover with good supportive measures alone. If a patient starts to deteriorate after apparent recovery or is deteriorating despite good supportive care, a pharmacobezoar should be suspected. In rare cases endoscopy may be necessary to remove the bezoar (1). If hypotension fails to respond to fluids or if the patient is already fluid-overloaded, a trial of peripherally acting vasopressors such as norepinephrine or phenylephrine is preferable for vasodilatory shock. Partial or full cardiopulmonary bypass or intra-aortic balloon pump therapy should be considered for hemodynamically unstable patients who fail to respond to vasopressors and inotropic agents. Barring hypoxic injury, full recovery can be expected once the drug is eliminated.

Patients with methaqualone poisoning may require pharmacologic paralysis for control of neuromuscular hyperactivity. Flumazenil, the benzodiazepine antagonist, has reversed CNS depression from zolpidem, zaleplon, zopiclone, baclofen, carisoprodol, chloral hydrate, and meprobamate (9,10). Routine use of flumazenil in the management of overdoses due to these agents requires some thought, as detailed in the discussion of its role in treatment of benzodiazepine toxicity (see Chapter 308). Sodium bicarbonate

should be the first line of treatment for dysrhythmias or conduction disturbances associated with orphenadrine. Physostigmine may be useful to control severe anticholinergic effects associated with orphenadrine and cyclobenzaprine (see Chapter 344). There is no specific antidote for baclofen toxicity.

The anticholinergic properties of cyclobenzaprine, glutethimide, and orphenadrine may slow absorption and lead to delayed gastric emptying, so activated charcoal may be used hours after ingestion depending on the mental status of the patient. Fluids should be given with caution in treating the hypotensive effects of meprobamate, because its myocardial depressant properties increase the risk of pulmonary edema. The use of extracorporeal elimination may be useful in the treatment of life-threatening meprobamate overdoses unresponsive to supportive measures.

Ventricular dysrhythmias from chloral hydrate are often refractory to treatment. Lidocaine, magnesium for torsades de pointes, β-blockers, and overdrive pacing have been used with success. Excess stimulation or manipulation of the patient, as well as catecholamine pressor agents, should be avoided to decrease the risk of precipitating dysrhythmias. Hemodialysis may be considered in cases of profound hypotension and unstable dysrhythmias.

CRITICAL INTERVENTIONS

- Establish intravenous access, cardiac monitoring, and maintain airway patency and respirations with endotracheal intubation and mechanical ventilation if necessary.
- Administer norepinephrine or phenylephrine for hypotension refractory to IV crystalloids.
- Administer intravenous sodium bicarbonate if QRS prolongation is present.
- Consider the use of flumazenil in selected cases when seizure is low risk to reverse toxicity from zolpidem, zaleplon, zopiclone, ezopiclone and possibly others.
- Consider cardiopulmonary bypass, intra-aortic balloon pump, and hemodialysis in severe poisoning refractory to standard therapy.

DISPOSITION

Patients with mild symptoms may be observed in the emergency department until asymptomatic, depending on the duration of action (Table 310.1) of the offending agent(s). Patients with moderate or severe symptoms require intensive care admission for close monitoring, and supportive care is necessary. Patients with unstable vital signs should be transferred to a facility that is capable of intensive care for poisoning victims. Advanced life-support equipment and staff should accompany the patient during transfer.

TABLE 310.1
Data for Nonbarbiturate, Nonbenzodiazepine Sedative–Hypnotic Agents and Muscle Relaxants

	Half-Life (hr)	Protein Binding (%)	Vd (L/kg)	Renal Elimination (%)	Active Metabolite	Therapeutic Blood Level (μg/mL)	Toxic Blood Level (μg/mL)	Lethal Blood Level (μg/mL)

[c]Volume of distribution provided as total volume and not per body weight.

Common Pitfalls

- Failure to consider pharmacobezoar and continuing drug absorption in patients with progressive, prolonged, or cyclic coma (especially with glutethimide and meprobamate).
- Failure to identify that meprobamate induced hypotension may precede CNS depression.

- Failure to appreciate that baclofen, buspirone, methaqualone, carisoprodol, and agents with anticholinergic properties such as cyclobenzaprine, glutethimide, and orphenadrine can cause neuromuscular hyperactivity or seizures in addition to CNS depression.
- Failure to monitor for pulmonary edema during fluid resuscitation.
- Failure to anticipate and treat withdrawal syndromes in chronically dependent patients.
- Failure to appreciate that chloral hydrate-induced ventricular dysrhythmias are exacerbated by catecholamines and may respond to β-blocker therapy.

CHAPTER 311

Phenytoin

Ejaaz A. Kalimullah and Steven E. Aks

Phenytoin is one of the most commonly utilized anticonvulsants and has been commercially available in the United States since 1938. Initially known as diphenylhydantoin, phenytoin was first synthesized by Heinrich Blitz in 1908 (1). In 1938, Merritt and Putnam described the anticonvulsant properties of phenytoin, making it one of the earliest known anti-epileptics after the bromide salts and phenobarbital. Today, phenytoin remains in use for the treatment of tonic–clonic seizures, for the treatment of partial complex seizures, in the setting of traumatic brain injury, and in the setting of neurosurgical procedures. Although phenytoin has also been used with varying success for trigeminal neuralgia and neuropathic pain, it appears to be less effective for toxin-induced or alcohol withdrawal seizures (2).

Phenytoin is available in many forms, including extended- and immediate-release capsules, chewable tablets, suspension, and phenytoin sodium injection solution. The injection solution contains a 40% propylene glycol and 10% ethanol diluent which is adjusted to a pH of 12 using sodium hydroxide. Infusion-related cardiotoxicity and local tissue injury from extravasation and intramuscular (IM) injection are caused by the propylene glycol–containing alkaline diluent. Fosphenytoin is a phosphate ester prodrug of phenytoin approved for use in 1996. Fosphenytoin has a pH of 8.6 to 9.0, is more water soluble, lacks the propylene glycol diluent, and allows for both intravenous (IV) and IM administration. To avoid potential conversion errors, fosphenytoin is dosed using phenytoin equivalents (PE), where 1.5 mg fosphenytoin is equal to 1.0 mg phenytoin.

Therapeutic phenytoin plasma levels (10 to 20 μg/mL) can usually be achieved with an IV loading dose of 15 to 20 mg/kg of phenytoin or PE units of fosphenytoin. Because of propylene glycol cardiotoxicity, IV phenytoin should not be infused at a rate in excess of 50 mg/min (0.5 to 1.0 mg/kg/min in neonates and children). Fosphenytoin can be administered at a maximum rate of 150 PE units/min in adults or 3 PE units/kg/min in children. The adult maintenance dose of phenytoin is typically 4 to 6 mg/kg/d in divided doses.

In therapeutic oral use, peak plasma concentrations occur in 1.5 to 3 hours, with extended-release formulations producing peak levels at 4 to 12 hours (1). Oral overdoses may have erratic, incomplete, markedly delayed, and prolonged absorption (3). As with other drugs, ingested quantity, chronic therapy, co-ingestants, gut motility, and bezoar formation all influence toxicokinetics.

Fosphenytoin is converted to phenytoin by phosphatases in the blood and liver with a conversion half-life of approximately 15 minutes. Although peak serum levels of IV administered phenytoin are obtained at the end of the infusion, phenytoin levels should not be monitored following fosphenytoin infusion until conversion is complete at approximately 2 hours afterward (3). IM fosphenytoin is well absorbed and produces more sustained, albeit lower, blood levels when compared to IV therapy.

Phenytoin rapidly diffuses into tissues, particularly the central nervous system (CNS) and CNS levels equilibrate with the plasma compartment within 10 minutes of IV infusion (1). Phenytoin is 90% protein bound, primarily to albumin. Because only the 10% of free drug is active, altered plasma protein binding or decreased plasma protein concentrations as may occur with malnutrition or cirrhosis may reduce the threshold for toxicity. The apparent volume of distribution ranges from 0.4 to 0.6 L/kg in adults and is probably increased in overdose.

Phenytoin is metabolized by hepatic microsomal enzymes, primarily CYP2C9, resulting in the production of the inactive 5-(*p*-hydroxyphenyl)-5-phenylhydantoin (*p*-HPPH) metabolite. Phenytoin also undergoes enterohepatic recirculation. Cytochrome-P450–

mediated drug interactions can result in significant changes in phenytoin levels and result in toxicity (Table 311.1). The metabolism of phenytoin is a saturable process. At concentrations <10 μg/mL, there is first-order metabolism, with a fixed proportion being metabolized per unit of time and an approximate half-life of 6 to 24 hours (1). At concentrations in the high therapeutic range, the metabolic pathways become saturated, resulting in zero-order kinetics where a fixed amount of drug is metabolized per unit of time, and the "apparent half-life" increases as the concentration increases. This saturation most likely accounts for the wide range of "apparent half-lives" (7 to 60 hours) reported with therapeutic use and the prolonged elimination observed after overdose (4).

TABLE 311.1
Factors Influencing Phenytoin Kinetics

Pharmacokinetic Effects	Condition or Concomitant Drug Use	Pharmacologic Effect
Decreased protein binding	Acidosis	Increased risk for phenytoin toxicity
	Age (neonates)	
	Uremia	Higher free fraction of circulating phenytoin
	Hepatitis	
	Hypoalbuminemia	
	Valproic acid	
	Nonsteroidal anti-inflammatory agents	
Decreased clearance	Metabolic inhibitors (e.g., amiodarone, SSRIs [fluoxetine])	Increased risk for phenytoin toxicity
	Tamoxifen, isoniazid, disulfiram, ticlopidine	Accumulation of phenytoin during chronic dosing caused by prolonged half-life
	Genetic deficiency of liver enzyme system (CYP2C9 and CYP2C19 polymorphisms)	
Increased clearance	Hepatic enzyme inducers (e.g., phenobarbital, carbamazepine)	Loss of efficacy with risk for breakthrough seizures
	Ciprofloxacin, ethanol	Shortened half-life results in less accumulation during chronic dosing
	Pregnancy	

The mechanisms of the therapeutic and toxic effects of phenytoin are not fully understood. Phenytoin's anticonvulsant effects most likely arise from inhibition of neuronal high-frequency firing by reducing the ability of Na^+ channels to recover from inactivation. This use-dependent effect is caused by preferential binding to the inactivated state of the Na^+ channel.

Phenytoin toxicity occurs in a number of settings. Acute overdose can result from deliberate or unintentional oral ingestion, generally of >20 mg/kg. Exposure to phenytoin may also occur from the adulteration of illicit drugs, such as crack cocaine, and from the use

of imported medications containing undisclosed anticonvulsants. In such cases, nystagmus, ataxia, and vomiting may provide valuable clues to suggest phenytoin poisoning. Acute overdose also follows the iatrogenic infusion of excessive doses of phenytoin or fosphenytoin. Errors in prescribing or administering, as well as changes in dosing or formulation, may lead to inadvertent toxicity during chronic oral therapy.

Given the central role of cytochrome P450 enzymes in metabolizing phenytoin, a number of drugs (Table 311.1) can cause toxicity by altering the clearance of phenytoin. Amiodarone, cimetidine, cotrimoxazole, disulfiram, fluconazole, metronidazole, and various antidepressants can decrease clearance of phenytoin. In contrast, medications that induce the cytochrome-P450 system, such as alcohol, barbiturates, carbamazepine, theophylline, and rifampin, can increase the clearance of phenytoin. Failure to adjust maintenance doses of phenytoin downward when stopping therapy with a cytochrome-P450 inducer may cause phenytoin intoxication.

CLINICAL PRESENTATION

The predominant signs and symptoms of acute or chronic oral phenytoin overdose are related to CNS dysfunction. Effects such as nystagmus, nausea, vomiting, tremor, ataxia, diplopia, and dysarthria often reflect cerebellar and vestibular impairment; toxicity usually correlates with increasing plasma concentrations. Although some patients may tolerate and therapeutically require phenytoin levels >20 μg/mL, patients with underlying brain disease may become toxic at only slightly elevated drug levels. Although nystagmus is common as concentrations rise >20 μg/mL, the absence of nystagmus does not rule out toxicity. Horizontal, vertical, bidirectional, or alternating nystagmus can be noted with significant poisoning, but may disappear as CNS depression and depth of coma increase (4). At levels >30 μg/mL, ataxia, slurred speech, and tremor are common. As levels rise to >40 μg/mL, confusion, lethargy, and stupor may occur. Although progressive CNS depression is typical, fluctuating agitation and lethargy have also been described. With levels >50 μg/mL, marked CNS depression and

coma predominate; profound CNS depression is associated with hyporeflexia and depression of cranial nerve reflexes. Infrequently encountered CNS findings include choreo-athetosis, ballismus, opisthotonus, and dystonias (5). Focal neurological deficits may occur in patients with prior hypoxic or ischemic brain injury. Rare "paradoxical" seizures have been noted with phenytoin levels >30 to 50 μg/mL, typically in the setting of a pre-existing seizure disorder. In the setting of acute overdose, seizures should prompt a search for co-ingestants or physiologic derangements.

Cardiovascular toxicity is not a clinical concern following oral overdose (6), but is the major toxicity seen with rapid administration of IV phenytoin. Hypotension, apnea, bradycardia, asystole, and ventricular dysrhythmias occur at rates in excess of 50 mg/min (rates as low as 25 mg/min have been recommended for patients >50 years of age). Associated electrocardiographic (ECG) changes may include ST segment and T wave changes, as well as atrioventricular blocks. Although the propylene glycol diluent in phenytoin injection solution is believed to be the primary mediator of cardiovascular toxicity, there may be other mechanisms. Bradyasystolic arrest has occurred in infants following several-fold overdoses of IV fosphenytoin, which does not contain propylene glycol. Although the cardiotoxicity associated with IV phenytoin is usually transient and expected to dissipate after the infusion is stopped, the potential for sudden life-threatening toxicity is greatest within this setting.

Extravasation of phenytoin can cause skin and soft-tissue necrosis, compartment syndrome, gangrene, and may lead to limb loss. "Purple glove syndrome," which consists of progressive limb edema, bluish discoloration, pain, and blistering, may follow IV administration of phenytoin on a delayed basis, even in the absence of evidence of extravasation. Risk factors for "purple glove syndrome" include advanced age, use of large repeated doses, small gauge IV catheter use, and use of the same infusion site for multiple doses (7). This syndrome has not been reported with fosphenytoin.

An idiosyncratic anticonvulsant hypersensitivity syndrome may develop in patients taking phenytoin, typically developing weeks to months after the initiation of therapy. This syndrome often produces

multisystem involvement and may present with fever, rash, hepatitis, eosinophilia, blood dyscrasias, pneumonitis, myositis, vasculitis, and/or nephritis. Anticonvulsant hypersensitivity syndrome is thought to occur from the generation of toxic arene metabolites of aromatic anticonvulsants (carbamazepine, phenobarbital, and phenytoin) and is potentially life-threatening (8). Additional adverse effects of phenytoin include Stevens–Johnson syndrome, toxic epidermal necrolysis, and drug-induced lupus.

Death is rare after acute oral overdoses of phenytoin. Most fatalities involve co-ingestants or respiratory failure and its associated complications, and many of the deaths reported in the medical literature predate modern intensive care and supportive care (5). Fatal cases are usually associated with phenytoin levels in excess of 120 μg/mL (3).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of phenytoin intoxication includes other illnesses that can produce the typical constellation of nystagmus, ataxia, dysarthria, and mental status changes. Other anticonvulsants can produce similar signs and symptoms and are often utilized by patients with epilepsy. Similarly, an overdose of sedative-hypnotic agents, ethanol, muscle relaxants, or psychiatric medications such as lithium, cyclic antidepressants, or the SSRIs can produce a comparable clinical presentation. CNS pathology, particularly cerebellar infarction, hemorrhage, or neoplasm, should also be considered. Other diagnostic considerations include hypoglycemia, Wernicke encephalopathy, extrapyramidal disorders, seizure disorders, and postictal states.

ED EVALUATION

The time and quantity of ingestion should be the primary focus, but a history of seizure disorder and other medication use should also be sought. The examination should focus on the neurological system. The clinician should note the presence or absence of altered mentation, nystagmus, slurred speech, and ataxia.

Serum glucose and an ECG should be obtained in patients with an altered mental status or when there may be a co-ingestion of other substances. ECG screening may provide additional information when ingestion of psychotropic or cardioactive agents is being entertained. If the patient has a known seizure disorder but is taking unknown medications, phenytoin, phenobarbital, carbamazepine, and valproic acid are commonly prescribed medications for which blood levels can be measured. If medications are known, levels of the specific agents should be ordered. When levels are positive and the patient is either unreliable or may have attempted suicide, serial levels can establish a peak and declining trend. These levels should be clinically correlated with the patient's condition. Serum albumin level may be helpful in patients with nephrotic syndrome, malnutrition, or liver failure or who are otherwise at risk since hypoalbuminemic patients may exhibit toxicity at normal or minimally elevated phenytoin levels. Acetaminophen and salicylate levels are typically obtained in suicidal overdoses, as these agents are common co-ingestants. Routine laboratory studies and a pregnancy test in females of childbearing age may help for general supportive care.

KEY TESTING

- Blood glucose if altered mental status
- Serum phenytoin level(s)
- Serum albumin level in at-risk patients
- ECG in symptomatic patients

ED MANAGEMENT

Patients who develop hypotension or bradycardia during IV infusion should have the drip immediately discontinued. The drip rate and concentration should be checked. When vital signs are normalized, a slower infusion rate can then be continued with cardiac monitoring.

For oral overdose, the patient's airway, breathing, and circulation (ABCs) should be monitored and stabilized appropriately. Oral phenytoin overdose is rarely fatal with attentive supportive care, and cardiovascular toxicity is unlikely. An initial ECG should be obtained

to establish normal intervals, and cardiac monitoring should be initiated if there are any abnormalities. If there is significant ataxia or nystagmus or gait abnormalities, the patient should be protected from falls and should have frequent neurological reevaluations.

A single dose of activated charcoal is a reasonable method for gastric decontamination following oral exposure in patients without significantly depressed mentation. The use of multiple doses of charcoal, although of theoretical value, remains of unclear clinical utility (9). If the patient has an underlying seizure disorder, phenytoin should be administered to avoid allowing the phenytoin level to decreasing to less than the therapeutic range.

Although extracorporeal removal of phenytoin is rarely necessary given the efficacy of standard supportive care measures, high-flux hemodialysis may provide significant drug removal in selected cases of severe poisoning (10).

CRITICAL INTERVENTIONS

- Establish a peak and declining trend by following serial phenytoin levels in all potentially significant exposures.
- When loading phenytoin IV, the patient should have continuous cardiac monitoring, and extravasation must be avoided.
- Infusions should be stopped if there is evidence of bradycardia or hypotension.

DISPOSITION

Patients with no or minimal toxicity after a suicidal ingestion and a therapeutic peak phenytoin concentration can be cleared for psychiatric evaluation. Patients with elevated peak phenytoin levels and moderate to severe symptoms, such as ataxia, tremor, confusion, or stupor, require hospitalization. Patients admitted after oral phenytoin overdose can be admitted to nontelemetry settings (6), but should go to a setting where fall precautions can be instituted and frequent neurological checks can be performed. Only rare severely intoxicated patients will require an intensive care setting.

Nonsuicidal patients with mild symptoms and a reliable family support system can be discharged home with instructions to prevent falls. The family should also be counseled on holding doses for the next day or two as appropriate. More seriously intoxicated patients should be admitted to the hospital as above for supportive treatment.

Common Pitfalls

- Exceeding phenytoin IV infusion rates of 25 to 50 mg/min, causing hypotension and/or bradycardia.
- Causing phenytoin toxicity by not checking a drug level prior to giving a loading dose.
- Admitting all oral phenytoin overdoses to a telemetry setting. Cardiac toxicity is extremely rare, and this is generally not necessary.
- Failing to consider phenytoin toxicity and proceeding with imaging evaluation for other acute neurological conditions.
- Failing to recognize the anticonvulsant hypersensitivity syndrome.
- Failing to recognize the purple glove syndrome.

CHAPTER 312 Valproic Acid

Patrick M. Lank and Sean M. Bryant

Originally synthesized from a chemical found in valerian root, valproic acid has been in clinical use as an antiepileptic drug for over 45 years. Initially prescribed for a broad range of seizures, including absence, partial, and generalized tonic–clonic, valproic acid has also been used for the treatment of mania in bipolar disorder, migraine headaches, and neuropathic pain (1). Given valproic acid's multiple indications, particularly for psychiatric disorders, it is commonly encountered in both intentional and unintentional overdoses (2). In 2011, 8,052 toxic exposures to valproic acid were reported to US poison centers (more than carbamazepine and phenytoin combined) and were associated with more than 20 poison-related deaths in the same year (2).

Valproic acid is a simple branched chain carboxylic acid that is structurally dissimilar to other anticonvulsants. Antiepileptic effects of valproic acid come from various mechanisms including 1) increasing γ-aminobutyric acid (GABA) activity, 2) decreasing NMDA receptor–mediated glutamate activity, and 3) inhibiting voltage-gated sodium channels (3). Mechanisms related to valproic acid's newer uses as a mood stabilizer and adjunctive agent in pain syndromes are complex and yet to be defined (4).

Valproic acid (Depakene) is available as a syrup, capsule, and intravenous formulation (Depacon). Divalproex sodium (Depakote) is a 1:1 ratio of valproic acid and sodium valproate. It is packaged as a sprinkle, delayed- or extended-release capsule. Oral bioavailability is near 100%, and peak concentrations are reached within 6 hours for therapeutic dosing. In overdose, especially with

delayed- or extended-release formulations, initial levels may be undetectable, and peak levels are extended out as far as 18 hours or longer (4). The volume of distribution is small, and the drug is rapidly distributed throughout the body. Protein binding is significant, though this decreases in overdose. The half-life at therapeutic levels is 8 to 17 hours, but after overdose, it may be as long as 19 to 20 hours (5).

The bulk of valproic acid is metabolized by hepatic glucuronidation, and then its metabolites are largely excreted in the urine. Through multiple direct and indirect mechanisms, valproic acid interferes with the normal mitochondrial function in the urea cycle, leading to accumulation of ammonia. Carnitine is a required co-factor for the metabolism of ammonia as part of the urea cycle, but the use of valproic acid has been associated with carnitine depletion (6). This mechanism of carnitine depletion-related hyperammonemia is the physiologic basis for the potential use of supplemental carnitine in valproate-associated hyperammonemia.

CLINICAL PRESENTATION

Slow absorption delays the onset of symptoms. Central nervous system depression including coma is the predominant finding in severe valproic acid toxicity (7). Valproic acid toxicity may also cause nausea, vomiting, pancreatitis, hepatitis (although rare after acute ingestion), hemodynamic instability, and cerebral edema. Metabolic effects are seen with more severe toxicity and may include hypernatremia and lactic acidosis with an anion gap.

ED EVALUATION

Because valproic acid overdose primarily manifests as central nervous system depression, the airway must be carefully assessed. After completion of the primary survey and appropriate interventions, a detailed history should include whether the ingestion was accidental or intentional, the potential for co-ingestants, other medications the patient has had access to, time of ingestion, and apparent acute versus chronic ingestion. Physical

examination should focus on mental status. History provided by paramedics, friends, family, and old medical records is often helpful in the patient with altered mental status.

Serum valproic acid concentrations between 50 and 100 μg/mL are considered therapeutic, but the exact range depends on the laboratory-specific range. Although higher levels do not correlate exactly with clinical findings, some generalizations can be made. Levels <450 μg/mL are associated with less serious toxicity, and those >850 μg/mL are associated with critical illness including coma (7). This leaves a wide range of concentrations correlating with variable clinical effects, though it is clear that patients with levels between 450 and 850 μg/mL may also be critically ill. Slow absorption and late peak serum concentration of valproic acid mandates serial testing regardless of the presence or absence of symptoms.

DIFFERENTIAL DIAGNOSIS

The list of agents that can cause altered mental status is extensive (see Chapter 11, "Altered Mental Status and Coma"). Valproic acid intoxication can mimic most other central nervous system depressant drugs. Postictal states, metabolic derangements, central nervous system lesions, trauma, infection, hypoglycemia, and hypoxia may present similarly. Ammonia may be elevated in liver disease. The key to arriving at the correct diagnosis is a good history, exclusion of alternate etiologies, and serial serum valproic acid concentrations.

KEY TESTING

- CBC, chemistry (with anion-gap calculation), lactic acid
- Valproic acid concentration
- Ammonia level
- Liver function tests and lipase

ED MANAGEMENT

Aggressive supportive care and strict attention to airway and breathing is critical, with intubation and ventilation for airway compromise or respiratory depression. Prior to definitive airway management, naloxone and bedside glucose testing are appropriate in the undifferentiated comatose patient but not helpful for valproic acid.

Early decontamination may prevent absorption and subsequent toxicity, however an intact airway and mental status are required for this. For larger overdoses, activated charcoal is the preferred mode of decontamination, as it readily adsorbs valproic acid. Appropriate initial dosing of activated charcoal is in a 10:1 ratio to amount of drug ingested (e.g., 50 g of activated charcoal should be given for a 5 g ingestion), as tolerated, up to 100 g initially. Repeat dosing may be indicated if continued absorption is occurring.

Enhanced elimination with hemodialysis may result in lowering of drug levels, especially in cases where the valproic acid concentration is excessive (>850 mg/L). Hemodialysis should particularly be considered when there is renal insufficiency, significant electrolyte disturbance, or acid–base derangement (7).

L-carnitine has been used to hasten resolution of coma in patients with valproic acid–associated hyperammonemia (8). Although use of L-carnitine for valproic acid–associated hyperammonemia in the overdose setting has limited evidence, it is safe, has minimal side effects, and is a reasonable adjunct to therapy. Dosing recommendations vary, but 100 mg/kg intravenously (up to 6 g) over 30 minutes, followed by 15 mg/kg every 4 hours, is appropriate. The end point is clinical improvement or 3 days of therapy.

CRITICAL INTERVENTIONS

- Airway management for severely poisoned patients with depressed mental status
- For patients with overdose: electrolyte panel, liver function panel, ammonia level
- Monitor anion gap and lactate in critically ill patients

- *Serial valproic acid concentrations* in all patients with acute overdose
- Hemodialysis for renal failure
- l-carnitine for elevated ammonia

DISPOSITION

All patients with evidence of mental status decline or respiratory insufficiency warrant an intensive care unit admission with continuous cardiac monitoring and airway assessment. In suicidal patients, clearance for psychiatric admission should wait until a downward trend in valproic acid concentration is confirmed. Both therapeutic and subtherapeutic concentrations have been reported to steadily rise, with concurrent signs of significant poisoning after acute overdose (9). Patients should not be discharged until serum levels are falling based on serial levels, are in the therapeutic range, and the patient is asymptomatic.

Common Pitfalls

- Failure to detect a delayed rise of valproic acid levels. Serial levels are required.
- Failure to consider delayed onset of toxicity.
- Premature medical clearance.
- Failure to work up patients completely for alternate etiologies of abnormal mental status.

CHAPTER 313 Carbamazepine

Marco L.A. Sivilotti

Carbamazepine (CBZ) is used for the management of epilepsy, trigeminal neuralgia, chronic pain syndromes, and affective disorders. Its main actions are to reduce the permeability of neuronal membranes to sodium and potassium ions and to block norepinephrine reuptake. CBZ also has anticholinergic effects and is structurally related to the tricyclic antidepressants. Despite the structural resemblance between CBZ and imipramine, there is only partial overlap of their toxicities after overdose. Notably, CBZ has a much greater therapeutic index and is much safer.

CBZ is available in 100- and 200-mg immediate-release tablets, in 100- to 400-mg controlled-release tablets and capsules, and as a 100-mg/5-mL suspension. Oxcarbazepine, a newer, chemically related anticonvulsant, is discussed in Chapter 314. Although CBZ is almost completely absorbed, the rate of absorption can be erratic. Peak concentrations, usually found 4 to 8 hours after therapeutic dosing or liquid suspension ingestions, may be delayed 24 to 72 hours after massive ingestions of tablets and up to 106 hours with controlled-release preparations (1–3). At therapeutic concentrations (8 to 12 μg/mL), CBZ is 75% bound to plasma proteins, with a volume of distribution of 0.8 to 1.2 L/kg (adult). CBZ is predominantly metabolized by hepatic CYP 3A3 and 3A4 to CBZ-10,11 epoxide (CBZ-E), which in turn is metabolized and excreted in both urine and bile. CBZ-E is pharmacologically active, possessing anticonvulsant properties and adding to the toxic effect in overdose. Concentrations of CBZ-E are usually about 20% of those of CBZ.

CBZ induces its own metabolism. Consequently, patients naive to CBZ eliminate it with a half-life of 20 to 65 hours, much more slowly than chronic users (8 to 17 hours). The half-life of CBZ-E is 5 to 7 hours (4). Other anticonvulsants, such as phenobarbital, phenytoin, valproic acid, and felbamate, may further increase the metabolism of CBZ by heteroinduction. CBZ metabolism is inhibited by erythromycin, propoxyphene, isoniazid, calcium channel blockers, cimetidine, fluvoxamine, lamotrigine, ketoconazole, and other CYP 3A3 and 3A4 inhibitors, which can result in toxicity despite therapeutic CBZ dosing. After an overdose, even among patients on chronic therapy, serum CBZ concentrations fall slowly due to saturation of the rate-limiting epoxidation and ongoing gastrointestinal absorption.

In an adult patient not regularly taking CBZ, significant toxicity can be expected after ingestion of 20 to 30 mg/kg and life-threatening effects after 140 mg/kg. Ingestions of >20 g have resulted in death (5). Neurologically intact survival has been reported after an ingestion of 60 g of controlled-release CBZ (2) and after an ingestion of 34 g leading to prolonged asystole with 50 minutes of external chest compressions (1).

CLINICAL PRESENTATION

The clinical manifestations of CBZ toxicity involve four main areas: 1) central nervous system (CNS), 2) ocular, 3) cardiac, and 4) motor. Although a sequential progression is classically described, individual patients may present at any stage and at times progress rapidly to profound coma and cardiac instability (6). Initial CNS symptoms include restlessness, confusion, excitation, and aggression. Dizziness, ataxia, nystagmus, diplopia, nausea, and vomiting are often present. As toxicity progresses, drowsiness, coma, and respiratory depression may occur, often after several hours (2,5). Hypotension, global hypokinesia, and cardiac rhythm disturbances may be seen in severe poisoning (1,3,6). Loss of P waves, premature ventricular beats, QRS prolongation, and complete atrioventricular block have been described (3), as have

bradycardia, Adams–Stokes syncope, and ventricular standstill (1). Prolongation of the age-adjusted QRS interval is common in children (3). Severely poisoned patients may have fixed and dilated pupils and disconjugate gaze (1).

Abnormal motor findings include tremor, choreoathetoid movements, and hemiballismus. Reflexes may initially be hyperactive with clonus. Seizures can occur, usually in patients with an underlying seizure disorder (7). The electroencephalogram may show occipital δ activity (usually suggestive of a brainstem disorder) (3). In the deeply comatose patient, adynamic ileus, hypothermia, and pulmonary edema may be present (2). Complications include aspiration, resistant status epilepticus, and the sequelae of hypoxia and seizures (1,5). Hyponatremia may result from an antidiuretic effect in either acute or chronic overdoses. Acute intoxication may result in hypokalemia.

Confusion, lethargy, and ataxia are usually associated with peak plasma CBZ concentrations of about 20 μg/mL. Coma, hypotension, dysrhythmias, seizures, and death often occur with peak plasma concentrations, which may occur hours or days after ingestion, above 40 μg/mL (3,5,7). Initial drug levels correlate only weakly with clinical course and are imperfect prognosticators of outcome (2,4). Because of the long half-life after overdose and continued absorption over many hours, the clinical course is typically prolonged (1–3). Severely poisoned patients may require more than a week to make a full recovery. Cyclic coma, in which partial recovery is followed by a relapse into a coma, can occur as gastrointestinal absorption resumes after ileus resolves (7).

DIFFERENTIAL DIAGNOSIS

Mild poisoning may resemble hypoglycemia, neurologic disease, serotonin syndrome, or intoxication by ethanol. In severe poisoning, the clinical picture may mimic overdose with cyclic antidepressants, anticholinergic agents, or other anticonvulsants. Other physiologic depressants, coexistent trauma, and co-ingestions should also be considered. A prolonged postictal state in a patient with a history of

seizures should raise suspicion for poisoning with CBZ or another new anticonvulsant.

ED EVALUATION

A directed history should be obtained from the patient, prehospital care providers, or available friends and family members. Recent dosing changes or newly prescribed medications that may inhibit CBZ metabolism (e.g., erythromycin, propoxyphene, isoniazid, calcium channel blockers, cimetidine, fluvoxamine, lamotrigine, ketoconazole) should be identified. The physical examination should include a full set of vital signs; pupil position, size, and reactivity; bowel sounds; and a neurologic examination focused on level and content of consciousness, responsiveness to stimuli, reflexes, motor tone, and cerebellar function. A 12-lead electrocardiogram (ECG), cardiac monitoring, and serum electrolyte and glucose determinations are indicated in symptomatic patients. Urine toxicology testing is generally not useful; computed tomography scanning of the head may be helpful in cases of diagnostic uncertainty. CBZ can cause a falsely positive urine drug screen for tricyclic antidepressants due to the structural similarity.

Frequent measurements of serum CBZ concentrations are helpful to detect continued absorption in patients with acute overdose. Serial levels should be followed until the patient is asymptomatic and levels have clearly peaked and fallen into the therapeutic range of 4 to 12 μg/mL. Rebound in CBZ levels coinciding with clinical deterioration is well described. Serum CBZ and CBZ-E concentrations can be separately determined by high-performance liquid chromatography. Immunologic assays used in most centers cannot distinguish between CBZ-E and the parent compound, but quantification of CBZ-E is not necessary for clinical care of the patient (2,4).

KEY TESTING

- ECG for QRS prolongation

- Continuous cardiac monitoring if symptomatic or conduction abnormality
- Serial serum CBZ concentrations

ED MANAGEMENT

As always, airway has the highest priority since most deaths from CBZ overdose are from complications such as pulmonary aspiration and respiratory depression. Level of consciousness and vital signs should be monitored. Hypotension should be managed with intravenous fluids and, if necessary, invasive monitoring and pressors such as norepinephrine. Central venous pressure monitoring is recommended in such patients to avoid fluid overload, which can result from CBZ antidiuretic effect. Wide-complex cardiac dysrhythmias should be treated with hypertonic sodium bicarbonate as described for cyclic antidepressants (see Chapter 339). Aggressive resuscitation efforts, including prolonged chest compressions and extracorporeal circulatory support, have been used successfully for severe cardiogenic shock (1,3).

Activated charcoal (AC) is recommended for all symptomatic patients regardless of time after ingestion, and for others with significant recent ingestions by history. Multiple-dose activated charcoal (MDAC) therapy enhances the elimination of both CBZ and CBZ-E and should be instituted for patients with significant symptoms or CBZ levels above 20 μg/mL (8). MDAC should be continued until levels have fallen into the therapeutic range or lower for patients not dependent on the anticonvulsant properties of CBZ. Ileus after massive overdose may preclude or complicate MDAC (1,2).

Forced diuresis, peritoneal dialysis, and continuous renal replacement therapies are of limited value in CBZ poisoning (1). CBZ and CBZ-E are both filtered efficiently by high-flux hemodialysis (9,10), but only a relatively small proportion of the body burden is removed. Although charcoal hemoperfusion also clears CBZ from the blood (1,2), this modality is not available in most centers. Extracorporeal removal should only be considered for

patients with significant dysrhythmias, hypotension, or prolonged coma and extremely elevated CBZ levels despite MDAC.

CRITICAL INTERVENTIONS

- Obtain serial serum CBZ concentrations until values clearly peak and then fall into the therapeutic range.
- Check for other drugs that affect CBZ metabolism.
- Administer MDAC in patients with significant symptoms or CBZ concentrations above 20 μg/mL.

DISPOSITION

Patients who are symptomatic or who have a CBZ level >15 μg/mL should be admitted. Those with moderate or severe clinical toxicity, rising drug levels, or an abnormal ECG should be treated in an intensive care unit. Patients with intentional overdose should be evaluated for suicide risk.

Common Pitfalls

- Failure to appreciate that CBZ absorption is slow and erratic and that peak levels may not occur until many hours or days after acute overdose.
- Failure to appreciate that although CBZ is an anticonvulsant, overdose can cause or exacerbate seizures.
- Failure to appreciate that CBZ is structurally similar to cyclic antidepressants and can cause similar CNS and cardiovascular toxicity.
- Failure to appreciate that AC and MDAC may be useful, even many hours after ingestion.
- Failure to appreciate that CBZ has active metabolites and that toxicity may take days to resolve.

ACKNOWLEDGMENT

The author gratefully acknowledges the contributions of Andrew J. W. Heath to this chapter in previous editions.

CHAPTER 314

Newer Anticonvulsants

Zhanna Livshits

Epilepsy is a common neurologic disorder affecting approximately 2.3 million Americans, with an individual lifetime incidence of approximately 3% (1). Prior to 1993, anticonvulsant medications (now commonly referred to as the "older" or "traditional" agents) were limited to phenobarbital, phenytoin, carbamazepine, valproic acid, ethosuximide, and primidone. Although studies show similar efficacy among these agents, their use is often limited by adverse effects, unpredictable pharmacokinetics, and drug–drug interactions (2). The "newer" (second-generation) anticonvulsants appear to be well tolerated, with broader spectrums of actions against a number of different seizure types than the older drugs, fewer serious adverse effects, and fewer drug–drug interactions (Table 314.1). These newer anticonvulsants are involved in overdose with growing frequency. Patients with epilepsy have a 10-fold greater suicide rate (11.5%) than the general population (1.1% to 1.2%) (3), and each of the anticonvulsants discussed in this chapter carries an FDA warning of an increase in suicidal thoughts and behavior in patients taking these medications. This is compounded by off-label use including for chronic pain syndromes and psychiatric disorders.

TABLE 314.1
Anticonvulsants Introduced in the United States Since 1993

Drug	Indications	Dosage Range	Pharmacokinetics	Drug Interactions	Amenability for Hemodialysis	Toxic Dose	Serious Effects, Reported
Felbamate (Felbatol) Chemical class: dicarbamate	Adults: **refractory** partial seizures with/without generalization Pediatrics: **refractory** Lennox–Gastaut syndrome, partial and generalized seizures	Adults (>14 yrs): 1,200–3,600 mg/d Pediatrics: (2–14 yrs): 15–45 mg/kg/d Dose adjustment with renal impairment	Oral bioavailability: 90% $t_{1/2}$: 20–23 hrs V_d: 0.7–1.0 L/kg Protein binding: 20–25% Metabolism: hepatic Excretion: 90% renally, 40–50% unchanged	Increases concentration of phenytoin, phenobarbital, and valproate; Decreases carbamazepine Felbamate clearance is increased by carbamazepine and phenytoin and decreased by valproate	Not established as effective means of elimination	Not established in humans	Aplastic anemia Hepatic failure Crystalluria and renal failure
Gabapentin (Neurontin) Chemical class: GABA analog	Adults: partial seizures with secondary generalization and postherpetic neuralgia, off-label for pain syndromes, e.g., diabetic neuropathy Pediatrics: partial seizures	Adults (>12 yrs): 900–3,600 mg/d divided into tid dosing Pediatrics: (3–12 yrs): 10–40 mg/kg/d Dose adjustment with renal impairment	Oral bioavailability: 27–60% $t_{1/2}$: 5–7 hrs V_d: 0.8–1.3 L/kg Protein binding: <3% Metabolism: not metabolized Excretion: 75–80%	Hydrocodone and morphine decrease gabapentin clearance	Dialyzable; consider in severely renal-impaired patients if benefits of procedure outweigh risks	Not established in humans	Altered mental status, coma, respiratory depression, myoclonus is more common with renal impairment
Lamotrigine (Lamictal) Chemical class: phenyltriazine	Adults: bipolar disorder, partial and generalized seizures, Lennox–Gastaut syndrome Pediatrics: Lennox–Gastaut syndrome, partial and generalized seizures	Adults: 25–500 mg/d Pediatrics: 0.15–15 mg/kg/d Dose adjustment with renal and severe hepatic impairment	Oral bioavailability: 98% $t_{1/2}$: 12–62 hrs V_d: 0.9–1.3 L/kg Protein binding: 55% Metabolism: extensively hepatic; Excretion: 98% renal	Acetaminophen, carbamazepine, oral contraceptives, phenobarbital, and phenytoin enhance lamotrigine clearance; Valproate decreases lamotrigine clearance	May be amenable to hemodialysis (HD); however, not established as effective means of elimination	Overdoses up to 15 g have been reported to result in fatalities	Lethargy, ataxia, nystagmus, encephalopathy, coma, seizures; conduction disturbances with PR and QRS prolongation; rash with therapeutic dosing or chronic overdose
Levetiracetam (Keppra) Chemical class: pyrrolidine derivative	Adults: partial, myoclonic and generalized seizures Pediatrics (4–16 yrs): myoclonic seizure (>12 yrs), partial and generalized seizure	Adults: 1,000–3,000 mg/d Pediatrics: 20–60 mg/kg/d (maximum dose: 3,000 mg/d) Dose adjustment with renal impairment	Oral bioavailability: 100% $t_{1/2}$: 6–8 hrs V_d: 0.7 L/kg Protein binding: <10% Metabolism: enzymatic hydrolysis Excretion: 95% in urine (66% unchanged drug and 24% inactive metabolite)	Does not induce hepatic enzymes	Approximately 50% removal by 4 hrs HD	Not established in humans	Altered mental status, behavioral changes (aggression, psychosis)
Oxcarbazepine (Trileptal) Chemical class: iminostilbene derivative	Adult: partial seizures Pediatrics (4–16 yrs): partial seizures	Adults: 600–2,400 mg/d Pediatrics: 8–10 mg/kg/d maximum dosing depends on patient's weight Dose adjustment with renal and severe hepatic impairment	Oral bioavailability: >95% $t_{1/2}$: oxcarbazepine 2 hrs; MHD (active metabolite) 9–11 hrs; V_d: oxcarbazepine 3–15 L/kg, MHD, 0.7 L/kg Protein binding: 40% Metabolism: extensively hepatic Excretion: 95% in urine	Inhibits the metabolism of phenobarbital and phenytoin Carbamazepine, phenytoin, and phenobarbital increase oxcarbazepine clearance May decrease oral contraceptive efficacy	Not established as effective means of elimination	Not established in humans	Lethargy, nausea, dizziness, ataxia, seizures, hyponatremia, bradycardia, hypotension, rash
Pregabalin (Lyrica) Chemical class: GABA analog	Adults: partial seizures, postherpetic neuralgia, diabetic neuropathy, neuropathic pain with spinal cord injury, fibromyalgia Pediatrics: not established	Adults: 150–600 mg/d Pediatrics: Not established Dose adjustment with renal impairment	Oral bioavailability: >90% $t_{1/2}$: 5–6 hrs V_d: 0.5 L/kg Protein binding: none Metabolism: hepatic negligible Excretion: 90–99% unchanged in urine	Does not induce hepatic enzymes	Amenable to HD; approximately 50% is removed within 4 hrs HD	Not established in humans	Lethargy, somnolence, coma, myoclonus
Tiagabine (Gabitril) Chemical class: nipecotic acid derivative	Adults: partial seizures Pediatrics (>12 yrs): partial seizures	Adults: 4–56 mg/d Pediatrics: >12 yrs, 4–32 mg/d (not approved <12 yrs) Dose adjustment with renal and hepatic impairment	Oral bioavailability: >90% $t_{1/2}$: 7–9 hrs V_d: 0.8–2.1 L/kg Protein-binding: 96% Metabolism: extensive hepatic Excretion: fecal 63%, renal 25%	Carbamazepine, phenobarbital, and phenytoin, increase tiagabine clearance	Not dialyzable	Not established in humans	Lethargy, coma, seizures with/without status epilepticus, agitation, myoclonus

Drug	Indications	Dosage Range	Pharmacokinetics	Drug Interactions	Amenability for Hemodialysis	Toxic Dose	Serious Effects, Reported
Topiramate (Topamax) Chemical class: sulfamate-substituted monosaccharide	Adults: partial and generalized seizures, Lennox–Gastaut syndrome, migraine prophylaxis Pediatrics: Lennox–Gastaut, partial seizures, generalized seizures	Adults: 25–400 mg/d Pediatrics: 1–3 mg/kg/d to 5–9 mg/kg/d Dose adjustment with hepatic impairment	Oral bioavailability: 75–80% $t_{1/2}$: 21 hrs V_d: 0.6–0.8 L/kg Protein binding: 15–41% Metabolism: hepatic, small extent Excretion: 70%, most unchanged in urine	Phenytoin and carbamazepine increase topiramate clearance Contraindicated with carbonic anhydrase inhibitors May decrease oral contraceptive efficacy	Amenable to HD	Not established in humans	Lethargy, dizziness, ataxia, oligohidrosis and hyperthermia, acute angle closure glaucoma, non-anion-gap metabolic acidosis
Vigabatrin (Sabril) Chemical class: GABA derivative	Adults and Pediatrics: refractory complex partial seizures, infantile spasms	Adults: 1–3 g/d Pediatrics: (10–16 yrs): 500 mg/d increase in dose is weight-based; Pediatrics: (1 mo–2 yrs): 50–150 mg/kg/d Dose adjustment with renal and severe hepatic impairment	Oral bioavailability: 50–65% $t_{1/2}$: 5.7 hrs for infants; 9.5 hrs for children, 10.5 hrs for adults V_d: 1.1 L/kg Protein binding: none Metabolism: hepatic, minimal Excretion: 95% renal	Decreases phenytoin plasma concentration	Dialyzable; warrants risk/benefit analysis following overdose	Not established in humans	Fatigue, dizziness, coma, psychosis, vision loss
Zonisamide (Zonegran) Chemical class: sulfonamide	Adults: partial seizures Pediatrics (>16 yrs): safety and effectiveness not established	Adults and pediatrics (>16 yrs): 100–400 mg/d divided into bid dosing Dose adjustment with renal and severe hepatic impairment	Oral bioavailability: >90% $t_{1/2}$: 63 hrs V_d: 1.45 L/kg Protein binding: 40%; extensively bound to erythrocytes Metabolism: hepatic Excretion: 62% renal, 3% fecal	Carbamazepine and phenytoin increase zonisamide clearance	Unknown	Not established in humans	Lethargy, coma, seizures, respiratory depression, bradycardia, hypotension, aplastic anemia, oligohidrosis and hyperthermia, nephrolithiasis, SJS/TEN Avoid in sulfa allergy

$t_{1/2}$, serum half-life; V_d, volume of distribution.
Table adapted from individual medication package inserts.

Although better tolerated than the older agents, overdose may be associated with significant morbidity and mortality. US poison centers reported 32,882 cases of exposures to these "newer anticonvulsants" in 2012, an increase from 22,182 cases in 2005 (4). Of these, 142 were classified as having a major outcome (defined as life-threatening or resulting in significant residual disability or disfigurement), and there were 4 deaths (4).

The newer anticonvulsants, each with its unique mechanism of action and pharmacologic profile, are FDA-approved as adjunctive treatment of partial seizures in adults (2). Felbamate, gabapentin, lamotrigine, levetiracetam, oxcarbazepine, topiramate, and vigabatrin are also used to treat partial seizures in children (5).

Felbamate (Felbatol), the first of the second-generation anticonvulsants, is used only in refractory cases of partial and generalized seizures, because of associated high morbidity and mortality from aplastic anemia and hepatic failure. The exact anticonvulsant mechanism is unknown but may entail neuronal sodium-channel blockade, calcium-channel blockade, as well as

glutamate antagonism at *N*-methyl-D-aspartate (NMDA) and α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA)/kainate receptors (6).

Gabapentin (Neurontin) is commonly prescribed for seizures and postherpetic neuralgia, although off-label uses comprise more than 80% of prescriptions (6). Its mechanism of anticonvulsant action remains unknown but is thought to involve a unique receptor in the brain (5,6). Although it is a structural analog of the neurotransmitter γ-aminobutyric acid (GABA), gabapentin neither interacts with GABA receptors nor modulates GABA metabolism.

Lamotrigine (Lamictal) is a phenyltriazine derivative structurally unrelated to other currently available anticonvulsants. Its exact mechanism of action is unknown. Studies suggest that lamotrigine's antiepileptic effect results from stabilization of neuronal membranes through the inhibition of voltage-dependent sodium channels and, to a lesser extent, calcium channels (5,6).

The exact mechanism of action of levetiracetam (Keppra), a pyrrolidine analog, is also unknown, but antagonism of *N*-type calcium channels and presence of a unique binding site, the synaptic vesicle protein SV2 A, have been suggested (5).

Oxcarbazepine (Trileptal), an iminostilbene derivative, is a keto-derivative of carbamazepine. Oxcarbazepine is a prodrug with a pharmacologically active 10-monohydroxy metabolite (MHD). Although the exact mechanism is unknown, oxcarbazepine may exert its anticonvulsive effects via blockade of voltage-sensitive sodium channels, enhanced potassium conductance, and modulation of high-voltage calcium channels (5,6).

Pregabalin (Lyrica), like gabapentin, is a structural analog of GABA but does not bind to the GABA receptor and does not modulate neuronal GABA activity. Pregabalin and gabapentin are pharmacologically indistinguishable. Modulation of calcium influx through voltage-gated neuronal calcium channels is the proposed mechanism of both anticonvulsive and nociceptive action (5).

Tiagabine (Gabitril) is a potent and selective inhibitor of the GABA transporter. It prevents GABA uptake in neuronal and glial cells, resulting in elevated GABA concentrations in the synaptic cleft (5,6).

Topiramate (Topamax) is structurally similar to the carbonic anhydrase inhibitor acetazolamide. Topiramate's anticonvulsant effects are due to several mechanisms, including inhibition of voltage-sensitive sodium and calcium currents, potentiation of GABA activity, and blockade of AMPA/kainate type glutamate receptors (5,6).

Vigabatrin (Sabril) is a synthetic GABA derivative that irreversibly inhibits GABA transaminase, thus inhibiting GABA metabolism and increasing central nervous system (CNS) GABA concentration (5).

Zonisamide (Zonigran) is a sulfonamide with a broad spectrum of anticonvulsant activity. Although the exact mechanism of action is unknown, in vitro analysis demonstrates blockade of voltage-sensitive sodium channels, calcium currents through T-type calcium channels, and enhancement of both dopaminergic and serotonergic neurotransmission (5).

CLINICAL PRESENTATION

Although the chemistry and pharmacology of each of the new anticonvulsants is unique, CNS effects usually predominate following overdose. Common symptoms include dizziness and lethargy.

Adverse effects may be seen in both therapeutic dosing and overdose. Most of the anticonvulsants discussed in this chapter are well tolerated following overdose and respond to supportive care. The unique clinical characteristics of each drug are discussed below.

Common effects following felbamate overdose include somnolence, ataxia, vomiting, and tachycardia. Documented fatalities from hepatic failure from aplastic anemia have occurred with therapeutic use. Acute renal failure and crystalluria are reported following overdose (7).

Isolated gabapentin overdose in otherwise healthy patients generally causes only mild toxicity. In a case series of 20 exposures to gabapentin ranging from 50 to 35,000 mg, drowsiness, dizziness, nausea and vomiting, tachycardia, and hypotension were the most common effects reported in symptomatic patients (8). Toxicity is more pronounced in patients with renal impairment. Altered mental

status and myoclonus have been described in patients with renal failure (5).

Lamotrigine overdose typically leads to neurologic and cardiac effects. The most common symptoms include lethargy and ataxia. Coma and seizures and QRS interval prolongation are the most consequential effects. PR and QT interval abnormalities have been reported. Patients taking lamotrigine therapeutically may develop a rash with progression to Stevens–Johnson syndrome (SJS) and toxic epidermal necrolytsis (TEN) (5). A few patients may develop drug reaction, eosinophilia, and hypersensitivity syndrome (DRESS), with rash, eosinophilia, and inflammatory organ changes.

Levetiracetam overdose is well tolerated, with few adverse effects. Transient alteration of consciousness, coordination problems, and behavioral abnormalities such as aggression and psychosis may be seen. Only one case report in an adult describes obtundation with respiratory depression following ingestion of 30 g (9).

Common clinical effects following oxcarbazepine overdose include fatigue, dizziness, ataxia, and nausea. The more serious effects include lethargy, coma, paradoxical seizures, bradycardia, hypotension, and hyponatremia (5). A drug rash progressing to SJS and TEN has been reported with therapeutic dosing (5).

Lethargy, somnolence, and coma are the most consequential effects following pregabalin toxicity (10). Myoclonus may be seen in patients with renal impairment (5).

Tiagabine toxicity is commonly associated with fatigue, dizziness, ataxia, and lethargy. Coma and agitation may be seen following overdose. Paradoxical seizures, both convulsive and nonconvulsive status epilepticus, have been described in postmarketing analysis of patients taking tiagabine therapeutically (5).

Topiramate toxicity causes sedation, word-finding difficulties, dizziness, and ataxia. Oligohidrosis and subsequent hyperthermia may be seen and are more common in children. Acute angle closure glaucoma, coma, and non–anion-gap hyperchloremic metabolic acidosis are the more serious effects with both therapeutic dosing and overdose (5).

Vigabatrin side effects commonly manifest as fatigue and dizziness. Coma may ensue following overdose. Psychotic behavior has been reported with therapeutic use as well as following overdose. Bilateral concentric visual field defects and progression to vision loss is the most consequential effect of therapeutic dosing.

Zonisamide toxicity causes sedation, ataxia, and nausea. The most important adverse effects seen in therapeutic dosing include SJS and TEN, aplastic anemia, oligohidrosis, and subsequent hyperthermia in the pediatric population, as well as nephrolithiasis. There are several reports of psychotic reactions after initiating zonisamide that resolve after discontinuation of the drug. Coma, seizures, respiratory depression, hypotension, and bradycardia are described following overdose (5). Cross-reactivity can occur in patients with sulfonamide allergy.

It should be noted that overdoses with the anticonvulsants can be complicated by co-ingestants. The potential for complications increases with more agents, including dose-dependent adverse effects, idiosyncratic reactions, drug–drug interactions, and long-term effects.

DIFFERENTIAL DIAGNOSIS

Numerous agents can cause CNS depression. These include the traditional anticonvulsants (carbamazepine, phenobarbital, phenytoin, and valproic acid), antidepressants, antipsychotics, antihistamines, alcohol, β-blockers, muscle relaxants, opioids, sedative–hypnotics, and many other agents. Medical causes such as stroke, trauma, intracranial hemorrhage, infection, electrolyte abnormalities, and cardiac dysrhythmia should be considered and differentiated from drug-induced effects.

ED EVALUATION

History includes the time of ingestion and type and amount of drug(s) taken, any treatment in the field, the onset and nature of symptoms, existing medical or psychiatric problems, and current drug therapy, particularly if the patient is on multiple medications for epilepsy. A rapid glucose concentration and vital signs, including

temperature, cardiac monitoring, and pulse oximetry, should be obtained.

Physical examination should focus on vital signs, cardiopulmonary status, and neurologic assessment. Skin assessment is important in lamotrigine, oxcarbazepine, and zonisamide exposure. Eye evaluation should be performed for visual complaints with topiramate and/or vigabatrin exposure. Seizure precautions should be instituted. Patients should be assessed for depression or suicide risk and those with intentional overdose require close observation while undergoing medical evaluation. Screening ECG for evaluation of PR, QRS, and QT intervals is important following lamotrigine exposure. Complete blood count (CBC) screens for aplastic anemia from felbamate and zonisamide. Basic metabolic panel (BMP) detects hyponatremia from oxcarbazepine exposure and hyperchloremia seen with topiramate-induced metabolic acidosis, and evaluates the renal function. Urinalysis may detect hematuria seen with nephrolithiasis from zonisamide and crystalluria following felbamate exposure. Liver function tests are necessary to screen for hepatotoxicity following felbamate exposure. Arterial blood gas is helpful in evaluating for topiramate-induced metabolic acidosis and seizure-induced lactic acidosis. EEG is instrumental in evaluation of nonconvulsive status. Patients with intentional overdose warrant an acetaminophen and salicylate concentration. Additional tests, such as CT head, may be warranted in evaluation of a patient with undifferentiated altered mental status or signs of trauma. Serum concentrations of anticonvulsants are not helpful in management of overdose.

KEY TESTING

- Specific drug levels are not helpful
- ECG, electrolytes, CBC, blood gases, EEG are necessary for certain anticonvulsants
- Additional tests may be useful for supportive care and to rule out other conditions

ED MANAGEMENT

Symptom-based supportive therapy is the cornerstone of managing second-generation anticonvulsant overdoses. Stopping the medication is the first step. Respiratory depression may warrant endotracheal intubation. Hypotension is usually responsive to intravenous crystalloids but may necessitate vasopressors, particularly in the presence of co-ingestants.

Intravenous sodium bicarbonate may be given for lamotrigine-induced QRS interval prolongation of >100 milliseconds. If a rapid bolus of 1 to 2 mEq/kg decreases the QRS duration, an infusion of sodium bicarbonate solution (150 mEq mixed in 1 L of D_5W) should be given.

Benzodiazepines are the first-line treatment for seizures, followed by phenobarbital and propofol for refractory cases or status epilepticus. First- or second-generation anticonvulsants have no role in anticonvulsant-induced seizures.

A single dose of oral activated charcoal may be considered in an awake patient shortly after a large ingestion. Gastric lavage is likely to be of more risk than benefit. Whole bowel irrigation may be considered for significant ingestions of extended-release preparations.

Hyperthermia, although rare, warrants rapid cooling with ice bath for goal temperature of <102 F within 20 minutes. Oxcarbazepine-induced hyponatremia should be treated with slow sodium repletion. In patients with intact mental status and absence of seizures, normal saline should be administered, followed by repeat lab testing. Patients with significant hyponatremia with either mental status changes or seizures may warrant hypertonic saline therapy. (See Chapter 210, “Disorders of Sodium”).

Topiramate-induced acute angle closure glaucoma should be treated rapidly.

Stopping topiramate usually alleviates the associated non–anion-gap hyperchloremic metabolic acidosis. The benefit of hemodialysis in overdose of second-generation anticonvulsants is unclear but may be considered for severe acid–base and electrolyte disturbances. Experience with intravenous lipid emulsion therapy (ILE) is limited

to case reports of lamotrigine overdose and cannot be routinely advised.

Discontinuing the medication is adequate for a drug reaction rash but patients with SJS or TEN may need admission to the burn unit. Patients with suspected DRESS syndrome require close observation, prompt discontinuation of the drug, and methylprednisolone therapy.

Consultations from neurology for continuous EEG monitoring may be helpful for status epilepticus and nonconvulsive status, from ophthalmology for visual changes following topiramate and vigabatrin exposures, from psychiatry for suicidal ideations or attempts, and with the Poison Control Center (1-800-222-1222) for new developments in management.

CRITICAL INTERVENTIONS

- Provide airway protection and respiratory support as clinically indicated.
- Administer intravenous fluids for hypotension.
- Administer intravenous sodium bicarbonate for prolonged QRS interval.
- Administer benzodiazepines as a first-line agent for seizures.
- Consider EEG monitoring in patients with persistent altered mental status.
- Hyponatremia should be corrected slowly with either normal saline in asymptomatic patients, or hypertonic saline in patients with altered mental status or seizures.
- SJS or TEN may warrant transfer to the burn unit for aggressive wound care.
- Consider contacting the Poison Control Center (1-800-222-1222) for the most recent developments in management.

DISPOSITION

Patients who remain completely asymptomatic after an observation period of 8 hours, or mild hyponatremia that corrects after normal saline may be medically cleared, unless a co-ingestant requires

further management. Patients with CNS or respiratory depression, status epilepticus, hemodynamic instability, or cardiac conduction disturbances should be admitted to an intensive care unit. Patients with an isolated seizure, renal insufficiency, or DRESS syndrome without hemodynamic instability may be observed on a medical floor. Evidence of TEN or SJS should prompt consultation with a burn unit. Consultation with the patient's physician is warranted if medication is discontinued. Patients and their families should be educated in cases where an unintentional exposure occurred to prevent re-exposure.

Common Pitfalls

- Failure to consider that, although rare, significant CNS depression can occur after overdose with second-generation anticonvulsants.
- Failure to assess for suicide risk, given the increased risk both with a diagnosis of epilepsy and with therapeutic use of second-generation anticonvulsants.
- Failure to consider that tiagabine may cause both convulsive and nonconvulsive status epilepticus.
- Failure to consider that cardiac conduction disturbances occur after lamotrigine overdose.
- Failure to recognize oxcarbazepine-induced hyponatremia.
- Failure to consider SJS and TEN following exposure to zonisamide, lamotrigine, and oxcarbazepine.
- Failure to appreciate topiramate-associated acute angle closure glaucoma and vigabatrin-associated vision loss.
- Failure to appreciate aplastic anemia as a complication of felbamate and zonisamide therapy.
- Failure to consider hyperthermia from oligohidrosis in pediatric patients with exposure to topiramate and zonisamide.
- Failure to consider the risks of medical comorbidities, drug interactions, and adverse effects.

PART 5 • ANTI-INFECTIVE AGENTS AND BIOCIDES

CHAPTER 315

Antimalarial Drugs

Suzanne M. Shepherd, Thomas Grosheider, and William H. Shoff

Malaria is one of the most important infectious diseases worldwide. Approximately 200 to 500 million new cases, and as many as 0.6 to 2.7 million deaths, occur each year in the 3 billion exposed. Malaria was eradicated in the United States (1947 to 1951), but 1,500 new cases annually, including 10% of cases of severe malaria with an increased risk of death, reported to the Centers for Disease Control (CDC) are associated with returning travelers and immigrants (see Chapter 193, " Parasitic Disease").

A higher risk of adverse drug reactions is tolerated in the treatment of malaria, with its high mortality if not expeditiously managed (1), and so the therapeutic ratios of some antimalarials are narrow and toxicity is likely when recommended dosing is exceeded. Patients at increased risk of developing severe adverse events are those at the extremes of age, HIV-positive, and G6PD deficient (2). Table 315.1 summarizes current common malaria chemoprophylaxis and treatment options in the United States.

TABLE 315.1
Common Chemoprophylaxis and Treatment of Malaria in the United States

Drug	Usage	Prophylaxis	Treatment	Safe in Pregnancy	Contraindications
Chloroquine (Aralen)	Sensitive, *Plasmodium falciparum, Plasmodium vivax, Plasmodium ovale, Plasmodium malaria*	(+)	(+)	(+)	Hepatic disease, persons with visual changes
Hydroxychloroquine sulfate (Plaquenil)	Chloroquine-sensitive *P. falciparum* and non-*falciparum* species	(+)	(+)	(+)	Hepatic disease, persons with visual changes
Mefloquine (Lariam)	Chloroquine-resistant *P. falciparum* and *P. vivax*	(+)	(+)	(+)	Seizure disorders, conduction disturbance, or history of significant psychiatric disease
Clindamycin (Cleocin)	Chloroquine-resistant *P. vivax* (in combination with quinine–quinidine)	(–)	(+)	(+)	Can be used with children <8 yrs
Doxycycline (Vibramycin)	Chloroquine-resistant *P. falciparum* and *P. vivax* (in combination with quinine–quinidine)	(+)	(+)	(–)	Lactating females and children, in patient <8 yrs, should be taken with food
Atovaquone/proguanil (Malarone)	Chloroquine-resistant *P. falciparum* and probably chloroquine-resistant non-*falciparum* species	(+)	(+)	(–)	Severe renal failure (CrCl <30 mL/min), should be taken with food
Primaquine (Palum)	Prolonged exposure to *P. vivax* or *P. ovale*	(+)	(+)	(–)	G6PD deficiency (can cause hemolysis), should be taken with food
Tetracycline	Chloroquine-resistant *P. falciparum* and *P. vivax* (in combination with quinine–quinidine)	(+)	(+)	(–)	Lactating females and children <8 yrs, should be taken with meals
Quinidine IV only (combine with doxycycline, clindamycin, or tetracycline)	Chloroquine-sensitive *P. falciparum* and non-*falciparium* species when parenteral drug needed	(+)	(+)	(–)	Conduction disorders, history of blackwater fever, thrombocytopenia, optic neuritis

Adapted from Griffith KS, Lewis LS, Mali S, et al. Treatment of malaria in the United States: A systematic review. *JAMA*. 2007;297:2264–2277; John CC. Drug treatment of malaria in children. *Pediatr Infect Dis J*. 2003;22:649–651.

Drug resistance has forced the use of new and fixed combinations of drug therapy. Older antimalarials are being used less frequently with less accidental or purposeful overdosing. Data on many of the newer drugs are less available, particularly in combination overdoses (3). Antimalarial agents currently in use in the United States include quinoline derivatives, dihydrofolate reductase inhibitors, antibacterials, artemisinin derivatives, and ubiquinone analogs (Table 315.2). Most antimalarial poisonings are the result of accidental childhood exposures or intentional adolescent and adult suicide attempts.

TABLE 315.2
Classification of Antimalarials

Quinoline Derivatives
Chloroquine
Hydroxychloroquine
Mefloquine
Quinidine
Quinine

Amino-4-quinolines
Amodiaquine

Amino-8-quinolines
Primaquine

Ubiquinone Analog–α-hydroxy-1,4-naphthoquinone
Atovaquone
(Atovaquone/proguanil [Malarone])

Pyrimethamine
(Pyrimethamine/dapsone [Maloprim])
(Pyrimethamine/sulfadoxine [Fansidar])
Sulfonamides

Antibacterials
Clindamycin
Doxycycline
Tetracycline

Artemisinin Derivates (Qinghaosu)
Artemether artesunate

Chloroquine, quinine, quinidine, amodiaquine, halofantrine, hydroxychloroquine, mefloquine, and primaquine are quinoline derivatives that cause severe toxicity in overdoses (1,4). The antimalarial quinine is an alkaloid derived from the bark of the Cinchona tree. Quinine has a black box warning in the United States due to hematologic toxicity. Quinoline derivatives carry an undeserved reputation as abortifacients (1). Both quinine and quinidine have been associated with immune thrombocytopenia caused by antibodies that bind only when the drug is present (5).

Chloroquine is usually well tolerated in prophylaxis and treatment doses. Mild side effects, including nausea and headache, may occur. Certain populations infected with malaria, such as Africans with G6PD and certain hemoglobin genotypes, may experience generalized pruritis via a nonallergic interaction. Chloroquine may worsen psoriasis and is rarely associated with psychosis and seizures. Acute chloroquine toxicity is usually seen when higher parenteral doses are administered too rapidly. Acute adverse reactions may

include central nervous system (CNS) and cardiovascular toxicity. Due to these side effects, chloroquine is contraindicated in those with a seizure disorder or generalized psoriasis.

Quinine is associated with (1) cinchonism, (2) hypotension, and (3) hypoglycemia. It has local anesthetic and irritant effects, some skeletal muscle-blocking action, vasodilatory effect due to its α-blocking activity, and acts centrally to cause emesis. Chloroquine and hydroxychloroquine share these effects and also act as respiratory depressants. Quinoline derivatives share several cardiac effects, causing negative cardiac inotropism, slowing depolarization and conduction, increasing action potential duration, and in overdose, lengthening the effective refractory period (widening QRS and QTc intervals) (1,3). Chloroquine in supratherapeutic levels causes direct arterial vasodilation. Nitric oxide and histamine release may mediate hypotension and postural hypotension. Case reports link both chloroquine and quinine to fatal cardiomyopathies (6). Chloroquine and hydroxychloroquine use may cause hypokalemia.

Oral quinine and chloroquine are rapidly absorbed in the small intestine, with 80% to 90% bioavailability and peak levels occurring 1 to 3 hours after ingestion. The apparent volume of distribution (VD) is 1.6 to 1.8 L/kg for quinine and 116 to 285 L/kg for chloroquine, with plasma protein binding of 89% and 55%, respectively. Due to high chloroquine tissue binding, brain concentration may be four times that of plasma, and may precipitate seizures (7). The VD for hydroxychloroquine is about 63 L/kg (8). Dose-related gastrointestinal (GI), CNS, and cardiovascular toxicity may result from excessive intravenous (IV) infusion or from accumulation following oral administration. Severe hypotension may develop if the drug is injected too rapidly. The toxic effects of quinoline derivatives are caused by their cardiac, cytotoxic, and irritant properties.

Ocular toxicity develops in 17% to 42% of patients with quinine poisoning and appears to be caused by a direct toxic effect on the photoreceptor and ganglion cell layers of the retina and can lead to blindness (9). The central 10% of the visual field is the initial site of toxicity. Cumulative dosing >800 g, age >70, and plasma

concentration of quinine >15 mg/L during overdose appear to be major risk factors for ocular toxicity. The risk of ocular toxicity is higher in dosing of quinolone derivatives used to treat rheumatologic disorders.

Chloroquine has a narrow margin of safety, with toxicity occurring at doses as low as 1.0 to 1.5 g, or 20 mg/kg. Doses >2 g in adults are almost always associated with toxic effects, and doses >5 g are usually lethal. Toxicity correlates with plasma quinine and chloroquine concentrations, and blood chloroquine levels >3 μg/mL are usually toxic. Death is likely if the level is >8 μg/mL. Chloroquine and hydroxychloroquine poisonings are associated with high fatality rates but are rare in the United States.

The toxic dose of quinine in adults ranges from 1.8 to 4.0 g. A single dose of quinine >3 g can cause serious and potentially fatal toxicity in adults, including CNS signs and seizures. Much smaller doses may be lethal in children. The therapeutic range of quinine is 5 to 15 μg/mL. Quinine levels as low as 2 μg/mL are associated with mild, reversible hearing loss. More toxic effects are seen with levels of 6 to 15 μg/mL. Cardiac arrhythmias, irreversible blindness, and death are reported with levels >15 μg/mL. Survival has occurred with levels as high as 23.5 μg/mL, but concentrations >13 μg/mL at 5 hours and 6 μg/mL at 20 hours predict severe toxicity.

Even therapeutic doses of primaquine can cause hemolytic anemia, including fatal hemolysis, in individual who are G6PD deficient. Methemoglobinemia can occur in those receiving therapeutic dosing, and can be severe in individuals with a congenital deficiency of NAD methemoglobin reductase. Rarely, usually with primaquine overdose, agranulocytosis or granulocytopenia, arrhythmia, hypertension, and CNS toxicity may occur. Hydroxychloroquine plasma concentration from 0.6 to 9.9 μg/mL is associated with severe toxicity. Amodiaquine has a similar mechanism of action as chloroquine and can cause hepatitis and agranulocytosis.

Mefloquine, also commonly used as chemoprophylaxis, may have cardiac depressant activity, and marked GI or CNS adverse effects, such as severe nausea, psychosis, odd vivid dreams, and seizures. Severe neuropsychiatric reactions requiring hospitalization, including

hallucinations and seizures, is reported in 1:15,000 to 20,000 of those taking mefloquine for chemoprophylaxis with more adverse reactions at higher treatment doses (1). Oral absorption is rapid, and half-life of 9 to 13 days follows hepatic biotransformation.

Pyrimethamine alone rarely causes toxicity, except for decreased hematopoiesis or skin rash. Excessive doses or overdose can cause megaloblastic anemia, similar to folate deficiency, hepatitis, serum sickness reactions, and severe to fatal skin reactions, such as erythema multiforme, Stevens–Johnson syndrome, and toxic epidermal necrolysis.

Atovaquone's, (a unique napthoquinone), most common reactions are maculopapular rash, fever, headache, apthous ulceration, and GI side effects including vomiting, abdominal pain, and diarrhea. Elevated transaminases and rare cases of hepatitis have been reported with the use of atovaquone–proguanil. Hepatic metabolism is the major path of elimination of proguanil, with 40% of the drug eliminated renally. The half-life of proguanil is 12 to 21 hours.

Artemisinin and its antimalarial derivatives artesunate and artemether are well-tolerated in both adults and children. IV artemether has been available in the United States since 2007 via an investigational new drug protocol through the CDC. Coartem, a fixed combination of artemether and lumefantrine, was FDA approved in 2009. Sesquiterpene alkaloids have been associated with allergic dermatoses and liver toxicity. Adverse effects of artemether and artemisinin derivatives include bradycardia, dizziness, rash, and fever. In combination with lumefantrine (Coartem), side effects also include abdominal pain, anorexia, nausea, vomiting, diarrhea, and headache. Human poisonings are rare, with the potential for GI, liver, cardiac, and CNS toxicity (10). Dizziness and GI disturbances are seen when the drugs are used orally. Toxicity occurs with long-term exposure rather than short-term peak concentrations (11).

CLINICAL PRESENTATION

Cinchonism is the most common early feature of quinine overdose, usually occurring within 4 hours of ingestion but as early as 2 hours and as late as 8 to 12 hours. Cinchonism can be seen with acute or

chronic poisoning and is noted in about 75% of patients. Mild cinchonism, including tinnitus, visual disturbances, high-tone deafness, headache, dysphoria, postural hypotension, nausea and vomiting, occurs frequently and resolves soon after the drug is stopped (1,6).

Cardiac toxicity after quinine is typically mild and dose related, producing sinus tachycardia and minor electrocardiographic (ECG) changes. However, ventricular arrhythmias, including torsades de pointes, significant conduction disturbances, and complete atrioventricular dissociation have been reported (1). ECG abnormalities include prolonged PR and QT intervals, ST- and T-wave changes, U waves, bundle-branch blocks, and QRS interval widening. Mefloquine has no effect on the QT interval. QT interval prolongation following artemether–lumafantrine use is similar or less than that with chloroquine, mefloquine, or combined artesunate and mefloquine, and significantly less than with quinine or quinidine (1). With massive exposures, convulsions, coma, respiratory depression, adult respiratory distress syndrome, and cardiac arrest may occur.

The incidence of early retinopathy in patients not monitored regularly is 10% for chloroquine, 3% to 4% for hydroxychloroquine, and 0.5% for advanced retinopathy (1,9). Visual disturbances can be delayed for 6 to 24 hours after ingestion and may present with progressive blurring of vision or sudden blindness. Dilated pupils that become fixed before vision loss occurs have been reported. Peripheral visual-field defects, color misperceptions, diplopia, and poor dark adaptation can precede the development of total blindness or can be transient. The fundus is usually normal at the onset of visual defects, but retinal arteriole constriction, macular edema, and a cherry-red macular spot can develop within hours, evolving into optic atrophy (1,9). Laboratory findings include hypoglycemia, hypokalemia, slight elevation of muscle enzymes, and thrombocytopenia. Hypoglycemia is quite common, and may occur as a result of quinine-induced insulin secretion. Quinine seldom induces abortion but is associated with fetal abnormalities and maternal deaths. Hydroxychloroquine should be used very carefully during pregnant individuals with malaria (12).

In contrast, chloroquine toxicity presents differently with a rapid onset of symptoms, severe cardiovascular effects, greater respiratory depression, marked hypokalemia, and milder and transient ocular and auditory toxicity. Cardiovascular collapse is common within 2 hours in serious overdoses and is a result of marked myocardial depression and ventricular dysrhythmias. Toxicity can be predicted by a prolonged QRS interval and hypokalemia, probably from intracellular shifts. Toxic effects are usually short-lived, despite persistently high plasma levels of the drug. Seizures may occur within a few hours after overdose, or be delayed to several weeks.

Other quinoline derivatives, such as primaquine, do not have severe cardiovascular toxicities but are associated with GI distress, hemolytic anemia, and methemoglobinemia.

Mefloquine overdoses produce neuropsychiatric manifestations including headache, dizziness, vertigo, seizures, affective disorder, paranoia, hallucinations, anxiety, sleep disturbances, suicidal ideation, and hearing loss. Nausea, vomiting, diarrhea, abdominal pain, and transient elevations in transaminase levels may be seen in a posthepatic syndrome caused by mefloquine-induced liver damage, coupled in some with thyroid inhibition. Because of the prolonged half-life, these adverse events can persist for weeks.

Myopathy is rare, but reported with the use of higher doses of quinolone antimalarials. Risk is increased with advanced age, underlying renal disease, diabetes, hypothyroidism, and liver disease. Patients may complain of painful or painless muscle weakness. Deep tendon reflexes and sensation may also be decreased. Creatine kinase (CK), aldolase, myoglobin, lactate dehydrogenase, aspartate aminotransferase, as well as phosphorus and potassium may be elevated, with CK the most sensitive but not specific (1).

Of the dihydrofolate reductase inhibitors, pyrimethamine is the most toxic and may cause ataxia, seizures, coma, blindness, and deafness and folate deficiency with megaloblastic anemia. Proguanil, another dihydrofolate reductase inhibitor, is one of the safest antimalarial drugs. GI distress with vomiting, diarrhea, and abdominal pain coupled with headaches, nausea, and hematuria has been reported with ingestions of 1 g or more. Therapeutic doses of

proguanil are associated with mouth ulcerations, GI distress, rash, and anemia.

Dapsone, another dihydrofolate reductase inhibitor, may cause acute methemoglobinemia and hemolytic anemia. A series of five HIV-positive patients developed methemoglobinemia while on primaquine and dapsone.

Massive doxycycline overdoses have resulted in precipitation of calcium and hypocalcemic death in animals. In humans, precipitation of calcium can lead to staining of teeth in children younger than 8 years. Doxycycline has been associated with Sweet syndrome, which is characterized by nonpruritic, painful, reddish nodules on the head, neck, chest, or upper limbs usually with fever, general malaise, and leukocytosis. Photosensitization is common. Benign intracranial hypertension, transient liver injury with transaminase elevation, GI upset, and esophageal ulcerations have also been reported with doxycycline.

Atovaquone, a novel hydroxynaphthoquinone, has produced minimal effects with overdoses up to 31.5 g. Methemoglobinemia has also been reported in a co-ingestion of atovaquone and dapsone.

DIFFERENTIAL DIAGNOSIS

Overdose with chloroquine and quinine can be confused with cerebral malaria. Quinoline derivative toxicity may resemble other agents that cause visual, auditory, or cardiac effects. Methanol, ergot derivatives, and heavy metals (e.g., lead and mercury) are in the differential diagnosis of visual disturbances. Unlike the quinolones, methanol is usually associated with a marked anion-gap acidosis and osmolal gap. Manifestations of cinchonism are similar to those of salicylate toxicity, but the latter also causes an elevated anion gap, and acid–base imbalances. Visual blurring may be seen with acute salicylate toxicity, but not visual loss. Quinidine, an isomer of quinine, causes similar cardiac effects but no visual deficits. Many drugs, such as the cyclic antidepressants, can cause similar cardiovascular and ECG effects, but these are not linked to auditory or visual changes. In patients with unexplained thrombocytopenia,

drug-induced (e.g., quinine, quinidine) immune-mediated causes should be considered.

ED EVALUATION

In the overdose or toxic patient who presents with visual, auditory, neuropsychiatric, and CV symptoms of unknown cause, a history of recent travel or the use or availability of antimalarial agents is suggestive. Attempted abortion by quinine should be suspected in a pregnant patient with these complaints. Physical examination and evaluation of the vital signs, cardiac rhythm and inotropy, auditory and visual acuity, pupillary size and reactivity, funduscopic findings, visual-field testing, and a neurologic examination, including cerebellar status, are important. An ECG should be obtained. Laboratory studies include rapid serum glucose assessment and monitoring, and blood levels of quinine, quinidine, salicylate, electrolytes, lactate, liver transaminases, blood urea nitrogen, CK, and a complete blood count. Myoglobin may be helpful in those with muscle weakness. Methemoglobin levels and hemolysis evaluation may be warranted for some agents. If available, electroretinograms and visual-evoked response testing may detect signs of retinal damage in quinine overdose.

KEY TESTING

- Rapid fingerstick serum glucose
- Basic metabolic and liver panel
- ECG and continuous cardiac monitoring
- Chromatography of drug levels if available

ED MANAGEMENT

A suspected ingestion of antimalarials requires immediate attention to the vital signs, cardiac monitoring, and potentially activated charcoal administration, depending on the time from ingestion. Prevention of absorption is most effective in the first hour and, if done early, may reduce peak plasma levels. The half-life in healthy volunteers taking a therapeutic dose of quinine was reduced by 50%

and, in overdoses, was shortened from more than 24 hours to 8 hours by repeated doses of activated charcoal. However, clinical outcome improvement has not been documented. Activated charcoal administration may be problematic because of the rapid onset of hypoglycemia, CNS depression, and seizures, particularly with chloroquine or quinine overdose.

Hypotension usually responds to IV fluids but may require a vasopressor (e.g., epinephrine, dopamine, or norepinephrine) and inotropes (e.g., dobutamine) (1). Hypotension, ventricular dysrhythmias, and cardiac conduction abnormalities often respond to serum alkalization to a pH of 7.5 with sodium bicarbonate administration, hyperventilation, or a combination of these. Lidocaine has been used, but may potentiate dysrhythmias and seizures. Class 1A and 1C antidysrhythmics, such as procainamide, disopyramide, and flecainide, should be avoided as they will potentiate quinine cardiotoxicity. Torsade de pointes is treated with IV magnesium, isoproterenol, or overdrive pacing. Serum potassium should be monitored, however overcorrection must be avoided as it will exacerbate the cardiac effects of chloroquine.

Benzodiazepines, combined with mechanical ventilation, and epinephrine have been helpful in the chloroquine-overdosed patient. High doses of diazepam (0.5 to 3 mg/kg IV) may counteract the hemodynamic and ECG changes associated with chloroquine toxicity. Other sedating and anticonvulsant agents, such as barbiturates, have been suggested but may risk exacerbation of the hypotension seen in severe chloroquine toxicity. Because the cardiac toxicity is similar to that seen with hyperkalemia, potassium replacement is not advised unless hypokalemia is severe.

Despite its theoretical potential for enhanced quinoline derivative elimination, acidification of the urine is unproven and may increase toxicity. Resin and charcoal hemoperfusion, hemodialysis, peritoneal dialysis, plasmapheresis, and exchange transfusion are ineffective because of protein binding and high volumes of distribution. Methylene blue should be given for methemoglobinemia (see Chapter 335).

Attempts at reversal of retinal arteriolar vasospasm by stellate ganglion block, anterior chamber paracentesis, retrobulbar injections, and systemic nitrate vasodilators are not effective and can produce significant complications. Hyperbaric oxygen (HBO) therapy has been promoted on the premise that retinal hypoxia secondary to arteriolar vasoconstriction contributes to visual loss. However, the reported benefit may represent natural recovery.

Recovery from quinoline overdose is usually gradual and complete, but visual defects from quinine may not completely resolve.

CRITICAL INTERVENTIONS

- Establish IV access, cardiac monitoring, and obtain an ECG and fingerstick glucose level.
- Protect the airway and assist ventilation in patients with seizures or CNS depression.
- Administer IV benzodiazepines and sodium bicarbonate as warranted to patients with severe chloroquine toxicity.
- Administer IV pressor to patients unresponsive to IV fluids.

DISPOSITION

Patients suspected of ingesting a toxic amount of a quinoline derivative should be observed for 6 to 8 hours. Symptomatic patients and any with cardiac conduction abnormalities should be admitted to an intensive care unit. An ophthalmologist should be consulted in patients with visual symptoms. Those with hearing deficit may need referral for audiology testing.

Common Pitfalls

- Failure to obtain a history of travel to a malarial area and/or antimalarial use or access, in patients with auditory, visual, cardiac, and neuropsychiatric abnormalities of unknown cause.
- Failure to appreciate that hypoglycemia and rapid neurologic and CV deterioration can occur after chloroquine overdose.
- Failure to appreciate that benzodiazepines can prevent dysrhythmias and seizures in patients with chloroquine overdose.

- Failure to consider multiple-dose activated charcoal therapy.
- Failure to appreciate that potassium replacement can exacerbate chloroquine-induced cardiac toxicity.

CHAPTER 316

Herbicides

Victor Tuckler

Herbicides are chemicals used to control unwanted vegetation. Most herbicides are applied as water-based sprays and are usually safe to use in agriculture. Synthetic organic herbicides can be sprayed using helicopters or airplanes. Herbicidal toxicity occurs by inhibiting cell division, photosynthesis, respiration, or amino acid production. Herbicides can mimic natural auxin hormones, which regulate plant growth, and cause deformities in new growth. There are several classes that pose a potential health hazard. This chapter focuses on three classes: (1) bipyridyls (paraquat, diquat); (2) chlorophenoxy acids (2,4-D, 2,4,5-T, Agent Orange); and (3) organic phosphorus compounds (glyphosate, glufosinate).

BIPYRIDYLS (PARAQUAT, DIQUAT)

Chemically paraquat (1,1′-dimethyl-4,4′-bipyridilium) and diquat (1,1′-ethylene-2,2′-dipyridilium) are classified as bipyridyl compounds. Paraquat is a rapidly acting, nonselective herbicide that is relatively inexpensive. It is used as a desiccant, defoliant, and plant growth regulator, classified by the Environmental Protection Agency as “restricted use,” which means it can only be applied by licensed individuals. Dermal or spray exposure generally causes only limited, localized injury but accidental or deliberate ingestions have a high mortality rate. The toxic effects of smoking paraquat-contaminated marijuana are either very rare or nonexistent and do not result in lung damage because the paraquat is pyrolyzed to dipyridyl during smoking which presents little toxic hazard.

Paraquat is a blue-green solution to avoid accidental confusion with other chemicals, with concentrations from 20% to 40% with dilutions of 0.1% to 0.5% typically made for formulations used in the field.

The LD50 for paraquat in humans is approximately 3 to 5 mg/kg, which translates into 10 to 15 mL of a 20% solution. Common brand names include Herbaxone, Gramoxone, Gramonol, Gramixel, Preglone, and Weedol. Diquat is available as Aquacide, Reglone, Reglox, and Weedtrim.

Paraquat is rapidly absorbed after ingestion. About 1% to 5% of paraquat is absorbed from the gastrointestinal (GI) tract. Peak concentrations are achieved within 2 hours. Dermal absorption through intact skin is minimal. Mucous membrane and ocular exposures may cause minimal systemic absorption, but local tissue damage may be significant. Inhalation of paraquat spray is unlikely to cause any systemic toxicity.

After absorption, paraquat is distributed to all major organ systems but it selectively accumulates in the lungs at concentrations 10 to 15 times greater than plasma levels. Peak lung concentrations are achieved 4 to 5 days after ingestion. Paraquat is actively taken up by type 1 and type 2 pneumocytes, the principal target organ for toxicity. The primary mechanism is through the generation of free radicals with oxidative damage to lung tissue. Oxygen potentiates paraquat-induced pulmonary fibrosis.

Paraquat is enzymatically reduced to an unstable free radical and then is reoxidized to produce a superoxide radical, causing lipid peroxidation, mitochondrial dysfunction, necrosis, and apoptosis. Free radical scavengers such as glutathione are rapidly overwhelmed. Over a period of hours to days, this mechanism leads to multiorgan failure. The organs most affected are the lungs, heart, kidneys, and liver. Aveolar epithelial destruction, pulmonary hemorrhage, and congestion progressing to obliterative fibrosis can occur in paraquat toxicity. The brain is usually not affected since paraquat does not readily cross the blood–brain barrier. Paraquat is not metabolized. Renal excretion is the major route of elimination for paraquat, occurring within the first 12 to 24 hours. However,

20% to 30% that may remain tissue-bound is excreted over 2 to 3 weeks. Damage to the proximal renal tubule can occur.

Diquat is a dibromide monohydrate salt related to paraquat with liquid concentrations from 15% to 25% and with dilutions of up to 0.23% for field use. It is a nonselective contact herbicide, desiccant, and plant growth regulator used as a general herbicide for control of broadleaf and grassy weeds in terrestrial noncrop and aquatic areas. It is also used as a desiccant in seed crops and potatoes. Diquat appears to involve mechanisms and clinical manifestations similar to those of paraquat but much less likely to cause pulmonary injury (1).

CHLOROPHENOXY ACIDS (2,4-D, 2,4,5-T, AGENT ORANGE)

Chlorophenoxy acid herbicides act as plant hormones (auxins) to limit the growth of broadleaf and woody vegetation. Chlorophenoxy acid herbicides include 2,4-D (2,4-dichlorophenoxyacetic acid), 2,4,5-trichlorophenoxyacetic acid (2,4,5-T), and 4-chloro-2-methyl-phenoxypropionic acid. Both 2,4-D and 2,4,5-T were used as defoliants in the Vietnam War, and referred to as Agent Orange, named for the orange stripes painted on the 55-gallon drums in which it was stored. Agent Orange was a 50:50 mixture of 2,4-D and 2,4,5-T but was contaminated with 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD, or dioxin), which is known to be carcinogenic and teratogenic in animals (suspected in humans). Only 2,4-D is currently available for general use in the United States. Brand names include Aqua-Kleen, Chloroxine, Esterom, Salvo, Weedar, Weed-B-Gone, and Weedone.

The GI absorption of chlorophenoxy acids is slow; peak blood levels may not occur for 12 hours or longer. 2,4-D has an apparent volume of distribution (Vd) of about 0.1 L/kg, with the highest concentrations found in the blood and heart. Elimination occurs primarily by renal excretion of unchanged 2,4-D, with a half-life of about 12 hours after low doses but longer after overdose and with renal failure.

Toxicity may involve interference with cell membrane lipid structure and function; formation of acetyl-Co-A analogs and choline esters with disruption of metabolic pathways and neurotransmission; and uncoupling of oxidative phosphorylation. Myotonia and rhabdomyolysis may result from increased activity of skeletal muscle mitochondrial enzymes. Serious poisoning almost always occur after suicidal ingestion of concentrated solutions. 2,4-D doses of 50 mg/kg produce mild toxicity, those of 100 mg/kg cause severe poisoning, and those of 250 mg/kg or more may be fatal. Pulmonary absorption from inhalation is possible, but unlikely to cause systemic toxicity. Although skin absorption is low, chronic dermal exposure may result in systemic toxicity.

ORGANIC PHOSPHORUS COMPOUNDS (GLYPHOSATE, GLUFOSINATE)

Glyphosate and glufosinate are phosphorylated glutamic acid analogs that inhibit plant enzymes involved in amino acid metabolism. Glyphosate (N-phosphonomethyl glycine) is sold in commercial preparations that also contain a surfactant, polyoxyethyleneamine (POEA), and is sold in the United States under the brand names Glifonox, Glycel, Rodeo, Rondo, and Roundup. Glufosinate (2-amono4-hydroxymethylphosphonyl butanoic acid) is marketed as Basta, Challenge, Finale, Hayabusa, and Ignite. These herbicides have limited oral and poor dermal absorption, undergo negligible metabolism, and are eliminated by urinary excretion. Glyphosate has a Vd of about 0.3 L/kg and a half-life of 2 to 3 hours. Glufosinate has a larger Vd (about 1.4 L/kg) and longer half-life (about 10 hours) which is increased in renal failure.

Although ingestion of commercial formulations clearly causes poisoning, and uncoupling of oxidative phosphorylation has been suggested as a mechanism, it appears that POEA, a nonionic surfactant with cationic (corrosive) effects, is actually responsible for GI, cardiovascular (CV), and pulmonary toxicity. Glyphosate and the accompanying surfactant (POEA) are also corrosive contact toxicants. Ingestion, aspiration, or prolonged cutaneous contact can

result in skin and mucous membrane irritation, edema, and ulceration.

Neurotoxic effects of glufosinate may be from stimulation of excitatory N-methyl-D-aspartate receptors or inhibition of glutamine acid decarboxylase and consequent decreased synthesis of the inhibitory neurotransmitter γ-aminobutyric acid (GABA), whereas CV toxicity appears to be as a result of the POEA component. In adults, the ingestion of 50 to 100 mL of an undiluted organic phosphorus herbicide–surfactant formulation is likely to cause mild poisoning, 100 to 200 mL may result in moderate to severe poisoning, and 200 to 300 mL or more is potentially fatal.

CLINICAL PRESENTATION

Paraquat

The toxicity of paraquat and diquat depends on the dose and primarily the concentration involved. Tachycardia and hypotension may occur as a result of the fluid loss due to GI caustic burns and hemorrhage. Tachypnea develops in patients who develop pulmonary injury. Oropharyngeal burns may result from ingesting paraquat or diquat. Mucosal edema of the tongue and oropharynx may also develop. The GI tract is also a site of initial injury to mucosal surfaces following ingestion. Severe corrosive corneal injury may result from eye exposure. Conjunctivitis and corneal scarring may occur after exposure.

Upper respiratory tract exposure may result in mucosal injury and epistaxis. Inhalation may lead to cough, dyspnea, chest pain, and pulmonary edema. Pulmonary toxicity represents the most lethal manifestation of toxicity from paraquat.

Acute pulmonary edema and early lung damage may occur within a few hours of severe acute exposures, and may progress despite treatment. The delayed toxic damage of pulmonary fibrosis most commonly occurs 7 to 14 days after ingestion and respiratory symptoms may persist for several weeks after inhalational exposure. Dermal caustic effects include local skin irritation and ulceration of epithelial surfaces. Concentrated solutions may cause dermal burns

that enhance absorption. Systemic toxicity due to dermal exposure through intact skin is uncommon. Local skin damage can cause a contact dermatitis. Prolonged contact will produce erythema, blistering, abrasion, and ulceration. CV effects occur from necrosis of the myocardium. Patients may develop hypotension due to fluid losses and cardiac dysrhythmias. Myocarditis and skeletal muscular necrosis can occur after ingestion.

Diquat and paraquat can produce GI symptoms such as nausea, vomiting, abdominal pain, and diarrhea. The toxicity is manifested by swelling, edema and painful ulceration of the mouth, pharynx, esophagus, stomach, and intestine. Corrosive injuries to the esophagus and stomach such as hemorrhage and perforations may occur. Hepatic failure due to centrilobular hepatocellular necrosis may occur 24 to 48 hours postingestion. Renal failure may occur postingestion due to acute tubular necrosis. Cerebral edema, lethargy, and coma occur in severe cases with either paraquat or diquat. Pontine purpura and brainstem infarct have occurred with diquat.

Diquat

Diquat is structurally similar to paraquat but is less toxic. Diquat is toxic to the kidneys and is much less likely to cause respiratory failure than paraquat, and it has not caused pulmonary fibrosis. Symptoms begin with GI effects similar to paraquat, but diquat does not produce pulmonary fibrosis. Local corrosive toxicity can occur after oral, dermal, inhalational, eye exposure to diquat-containing formulations. Burning in the mouth and painful ulcerations are common after diquat ingestion.

Chlorophenoxy Acid

The ingestion of concentrated chlorophenoxy acid herbicides may cause a burning sensation in the pharynx, chest, and abdomen. Vomiting occurs early and may be persistent. Agitation, confusion, headache, dizziness, lethargy, coma, and seizures may develop within a few hours after exposure. Cyanosis, flushed skin, and

diaphoresis have been reported. Pupils tend to be small but reactive. Opisthotonus, myoclonus, fasciculations, and muscle tenderness have been described. In severe cases, progressive tachycardia, hypotension, and hyperthermia may ensue. Early death may be from ventricular fibrillation. Eye, skin, and respiratory tract irritation may follow exposure by these routes.

Laboratory abnormalities include an increased anion-gap metabolic acidosis, hypoxia, hyperkalemia, hypocalcemia, leukocytosis, elevated creatine kinase, mildly elevated hepatic enzyme levels, and renal function disturbances. The ECG may show flat or inverted T waves. Although pulmonary edema and aspiration have been reported, the chest radiograph usually is normal. Nerve conduction and electromyographic studies may show evidence of peripheral neuropathy and myopathy.

In mild to moderate chlorophenoxy acid intoxication, recovery occurs within 2 to 3 days; in severe cases, it may take longer than 1 week. Coma and acidemia are poor prognostic signs. Neuritis and myopathy with limb pain, paresthesias, twitching, tenderness, and weakness may be delayed in onset and persist for several months.

Organic Phosphorus Compounds

Ingestion of concentrated solutions of organic phosphorus herbicides can cause acute GI and pulmonary injury, delayed CV toxicity, and secondary hepatic and renal dysfunction. Inhaled glyphosate can produce respiratory irritation. The respiratory irritation can cause a burning pain, rhinorrhea, upper airway edema, coughing, stridor, or laryngospasm; and the aspiration of ingested glyphosate can cause noncardiogenic pulmonary edema.

Glufosinate also causes neurologic toxicity, which can be delayed (4 to 36 hours after ingestion) in onset and progressive over 24 to 48 hours. Neurologic findings include ataxia, confusion, disconjugate gaze, nystagmus, tremors, central nervous system (CNS) depression ranging from drowsiness to coma with central hypoventilation and apnea, and seizures. Generalized seizures, invariably preceded by coma, are typically recurrent, and can last

for several days. Complications include hyperthermia, acidosis, and rhabdomyolysis.

Signs and symptoms of caustic injury to GI, pulmonary, CV, hepatic, and renal systems are similar to those described for bipyridyl and chlorophenoxy acid herbicides. Hypovolemic shock may result from GI fluid losses and sequestration. Cardiogenic shock can occur subsequently. Severe GI injury, respiratory failure, and cardiogenic shock are associated with a fatal outcome. Patients with coma or seizures can have prolonged amnesia, encephapathy, and myopathy with recovery taking weeks. Exposure to organophosphorus–surfactant herbicides that have been diluted for use may still cause eye, skin, and mucosal irritation, but systemic toxicity is unlikely.

DIFFERENTIAL DIAGNOSIS

The initial presentation may resemble that of other corrosive exposure. Caustic injury to mucosa and oropharyngeal membranes may be mistaken for diphtheria or ingestion of caustic agents. The rapid progression of multiorgan failure following serious paraquat ingestion may resemble sepsis, cardiogenic shock, or severe salicylate toxicity. Pulmonary fibrosis occurring may resemble silicosis, asbestosis, and sarcoidosis. The rapid progression of severe pulmonary fibrosis is highly characteristic of paraquat ingestion. Diquat is more likely to cause acute renal failure and paralytic ileus.

Acute corrosive exposures have been mistaken initially for HIV-related infections such as oral candidiasis and *Pneumocystis jiroveci* pneumonia (2).

Except with glufosinate, the CNS depression caused by herbicides is not associated with respiratory depression. Severe 2,4-D and glufosinate poisoning patients may present with coma, seizures, tachycardia, hypotension, fever, rhabdomyolysis, and metabolic acidosis. This presentation may be confused with septic shock, diabetic ketoacidosis, severe stimulant poisoning, and intoxications by methanol, ethylene glycol, and salicylates. Other uncouplers of oxidative phosphorylation, such as the dinitrocresol and

dinitrophenol herbicides and the pentachlorophenol fungicides, may produce similar presentations. Cresylic and phenolic herbicides may stain the skin yellow and cause dark-colored urine.

ED EVALUATION

The history should include the concentration, amount, and route of herbicide exposure. Determining whether the product was diluted prior to exposure and estimating the exposure time and dose are important prognosticators. Vital signs should include measurement of the oxygen saturation.

The physical examination should include inspection of exposed surfaces for evidence of corrosive injury. After irrigation, patients with eye exposures should have fluorescein and slit-lamp examinations. Patients with GI signs and symptoms should also have an ECG, chest radiograph, arterial blood gas analysis, pulmonary function tests, complete blood count, electrolytes, BUN, creatinine, glucose, amylase, liver function tests, cardiac enzymes, lactic acid, and urinalysis. Paraquat may cause hypokalemia, which indicates a poor prognosis. In a retrospective study, a lactate concentration above 4.4 mmol/L (40 mg/dL) in paraquat poisoning is associated with a fatal outcome (3). Chest radiograph may be normal initially but will become abnormal after time with paraquat ingestions. Toxicology screening tests are not helpful because herbicides are not detected by the methods used. The detection and quantitation of herbicides usually requires sending a blood specimen to a reference laboratory. Although results can confirm exposure, they will not be immediately available and, except for paraquat, they have no prognostic value and will not help with making treatment decisions.

Quantitative paraquat levels are predictive of prognosis. Plasma levels >2 mg/L at 4 hours and >0.1 mg/L at 24 hours usually indicate a fatal outcome (4). Arrangements for a quantitative paraquat level can be made by calling Zeneca Ag Products (24-hour emergency line 800-327-8633). A qualitative urine test detects paraquat concentrations >1 g/mL and confirms exposure but is not prognostic. It may be performed by adding 1 mL of a 1% solution of

sodium dithionite in 2 N sodium hydroxide to 10 mL of urine. A blue color indicates the presence of paraquat.

KEY TESTING

- Most patients will need electrolytes, myoglobin, blood gases, lactate, renal and liver function tests.
- Patients with paraquat exposures need pulse oximetry, and serial chest x-rays; paraquat levels can be sent out to assist in prognosis.

ED MANAGEMENT

Initial treatment for herbicide exposure should focus on decontamination and supportive care. There is no specific antidote for herbicide poisoning. Supportive care with appropriate airway management is vital. ED management of the patient with acute paraquat poisoning should avoid oxygen therapy unless there is confirmed hypoxia. Oxygen may exacerbate the oxygen-mediated cellular damage induced by the superoxide radical. The treatment of diquat poisoning is generally the same as that for paraquat poisoning.

Decontamination is paramount and healthcare workers need to protect themselves. Personnel involved in decontamination must wear appropriate personal protective equipment, including gloves, masks, gowns, and goggles, to protect their airways, skin, and eyes. All clothing is removed. Contaminated skin and eyes should be flushed with copious amounts of water for at least 15 minutes.

Gastric decontamination procedures have not been shown to alter poisoning morbidity or mortality.

Gastric lavage is not recommended routinely because of the possibility of increasing the risk of iatrogenic perforation in corrosive injuries.

Activated charcoal has been shown to be successful with some herbicide ingestions and can be useful if it can be given prior to the distribution of the majority of the herbicide. Activated charcoal can reduce the amount absorbed if given within 60 minutes, but there is

inadequate evidence to determine if it is effective later than this. The potential benefit of charcoal should be weighed against any risk for aspiration. The exception is in poisoning by paraquat, which is well adsorbed by activated charcoal, Fuller's earth, and food. Many experts recommend that because serious paraquat poisoning is catastrophic and irreversible, and has no effective antidote, all such patients be given 1 gm/kg of activated charcoal in water, even with late presentation. However, endoscopy will be difficult, and more likely to be indeterminate, after oral activated-charcoal administration.

In severe cases, endotracheal intubation may be required. The airway is at risk due to the corrosive action of concentrated glyphosate and paraquat solutions. When intubating patients with chlorophenoxy acid poisoning, a nondepolarizing neuromuscular blocker (e.g., rocuronium) may be preferable to succinylcholine because the neuromuscular effects of succinylcholine are similar to those caused by these herbicides.

Endoscopy is recommended for those with evidence of corrosive injury to the airway or upper GI tract. The presence of gastric or esophageal ulcers indicates a poor prognosis. Benzodiazepines, muscle relaxants, or therapeutic paralysis should be used for agitation, fasciculations, myoclonus, or muscle rigidity, particularly those with hyperthermia or rhabdomyolysis. Propofol, which has antioxidant activity, should be considered for intubated patients with paraquat poisoning. Active external cooling measures may be necessary with hyperthermia. Avoid the use of salicylates, which also cause uncoupling of oxidative phosphorylation.

Supportive care should include monitoring for and treatment of hepatic, renal, cardiac, and pulmonary dysfunction and fluid and electrolyte abnormalities. With the exception of paraquat poisoning, standard therapies are employed. Because oxygen increases the pulmonary toxicity of paraquat, concentrations $>21\%$ should be used only when the pO_2 falls below 50 mm Hg. Positive end-expiratory pressure may improve arterial oxygenation.

Urinary alkalinization may be helpful, but evidence to support this practice is limited (5). Sodium bicarbonate can be used to correct acidemia and enhance herbicide elimination in patients with chlorophenoxy acid poisoning (6). Chlorophenoxy acids have pK_a values between 1.9 and 4.8, and increasing the pH increases the ionized fraction and traps these compounds in the blood and urine, thereby preventing their tissue distribution and enhancing their renal excretion. Sodium bicarbonate should be given as a bolus to correct acidemia and as a constant infusion to alkalinize the urine. Alkaline diuresis decreases the half-life of 2,4-D by about 50%. Urine pH must be increased to 8.0 to enhance excretion significantly.

Extracorporeal elimination therapies are indicated for patients with severe paraquat, diquat, and chlorophenoxy acid poisoning or potentially lethal ingestions and progressive clinical toxicity. Charcoal or resin hemoperfusion are the procedure of choice for bipyridyls, although hemodialysis is preferred for chlorophenoxy acids. Early, prolonged hemoperfusion appears to be useful in removing paraquat and limiting systemic toxicity when started within 10 hours of ingestion (15 to 20 hours in the presence of renal failure) and performed 8 hours daily or continuously for 2 to 3 weeks. Hemodialysis and continuous arteriovenous hemofiltration also enhance the elimination of paraquat and may be useful if hemoperfusion is unavailable. Data are limited regarding the use of hemoperfusion in diquat poisoning.

Free radical scavengers and antioxidants have been used in an attempt to prevent pulmonary fibrosis paraquat poisoning, but their efficacy remains unproven (7). Given the lethality of this condition, however, the following treatments should be considered: corticosteroids, cyclophosphamide N-acetylcysteine, and vitamin E. S-carboxymethylcysteine (Loviscol) has been used when N-acetylcysteine is unavailable. Lung transplantation may be considered. Nitric oxide inhalation and extracorporeal membrane oxygenation might be useful as interim measures. The National Pesticide Telecommunications Network provides a 24-hour-a-day

consultation services (800-858-7378) and the regional poison center (1-800-222-1222) may provide additional guidance.

CRITICAL INTERVENTIONS

- Identify the herbicide and estimate the dose and concentration.
- Perform aggressive decontamination with activated charcoal for paraquat.
- Correct acidosis.
- Consider hemodialysis for renal insufficiency.

DISPOSITION

Inpatient management is warranted for all patients after herbicide ingestion. Dermal burns from paraquat should be admitted. Unless the exposure is minor and the severity of poisoning is mild, transfer to a tertiary care center and admission to an intensive care unit are advised.

Discharge from the hospital should occur in asymptomatic patients if toxic effects do not develop within a few days of exposure.

Common Pitfalls

- Underestimation of the potential toxicity of herbicides, particularly with intentional ingestions of concentrated solutions.
- Failure to appreciate that although concentrated herbicide formulations are highly toxic, the likelihood of serious toxicity is greatly diminished once they have been diluted for use.
- Failure to appreciate that prolonged observation is necessary to rule out toxicity in patients with ingestions of dilute herbicide and with significant skin exposures to paraquat.
- Failure to evaluate symptomatic patients for multisystem organ dysfunction, including metabolic disturbances and rhabdomyolysis.
- Failure to appreciate that the pulmonary toxicity of paraquat is potentiated by oxygen and that if supplemental oxygen is

needed, the lowest possible concentration should be administered.
- Failure to appreciate that extracorporeal removal can enhance the elimination of paraquat, diquat, and chlorophenoxy acid herbicides.

CHAPTER 317 Isoniazid

Alan D. Woolf

Isoniazid (isonicotinic acid hydrazide, INH), a derivative of vitamin B_3 (nicotinamide), has been used for the prophylaxis and treatment of tuberculosis (TB) since 1952. INH is a prodrug that becomes bactericidal when complexed with NADH intracellularly and activated into reactive species by catalase-peroxidase (KatG). The complex interferes with the synthesis of mycolic acid, a necessary cell wall constituent in *Mycobacterium tuberculosis*. Generation of nitric oxide may also contribute to isoniazid's antimycobactericidal activity (1).

With the resurgence of TB has come an increasing incidence in INH poisoning. There were 249 INH poisonings reported to US poison control centers in 2011, with more than 45% severe enough to require treatment in a health care facility (2). The incidence of self-poisoning is greatest among those adult populations with a high prevalence of both tuberculosis and depression (e.g., Native Americans, immigrant populations). INH is rapidly absorbed from the small intestine, within 30 to 60 minutes after ingestion. Recommended therapeutic doses in children are 8 to 12 mg/kg (maximum, 300 mg) daily, given orally or by intramuscular (IM) injection (3). Peak INH serum levels (therapeutic range, 5 to 8 μg/mL) are reached within 1 to 2 hours. The drug is minimally bound to plasma proteins and has a small apparent volume of distribution (0.6 L/kg). INH can be detected in such diverse bodily fluids as saliva, cerebrospinal fluid (CSF), and breast milk. Up to 36% of the drug may be excreted unchanged in urine (4).

Metabolism by acetylation in the liver yields inactive metabolites that are predominantly excreted in the urine. People with normal renal function excrete 50% to 80% of a therapeutic dose of INH within 24 hours.

There is great genetic variability in the metabolism of INH. Between 45% and 75% of Caucasians are “slow acetylators” and have a mean serum INH half-life of about 5 hours. By contrast, 95% of Inuits are “fast acetylators” and have an average serum half-life of 80 minutes. These differences are therapeutically important: slow acetylators can achieve sustained bactericidal drug levels on every-other-day dosage regimens, whereas fast acetylators have inadequate levels unless they receive the drug daily (4). INH can increase the clinical effects of warfarin, carbamazepine, phenytoin, cyclosporine, and theophylline by interfering with their metabolism. It may decrease the antifungal actions of ketoconazole and itraconazole.

Several mechanisms are responsible for the toxic effects of INH. With both acute poisoning and chronic therapy, INH hydrazone analogs arise spontaneously (especially in slow acetylators) and form rapidly excreted complexes with pyridoxine, leading to a pyridoxine deficiency. INH hydrazones also inhibit pyridoxine kinase, thereby decreasing the conversion of pyridoxine to its active cofactor form, pyridoxal phosphate. In acute overdoses, INH inhibits the pyridoxal 5-phosphate–dependent enzyme, glutamic acid decarboxylase (GAD), which decreases the conversion of glutamic acid to γ-aminobutyric acid (GABA). The decrease in GABA, an inhibitory neurotransmitter, causes seizures. Pyridoxine deficiency itself causes brain excitability and seizures.

INH is structurally similar to nicotinic acid, substituting for it in the synthesis of nicotinamide adenine dinucleotide (NAD), to produce an inactive coenzyme. Inhibition of NAD-dependent Krebs cycle enzymes may result in hyperglycemia, and inhibition of NAD-mediated conversion of lactate to pyruvate worsens the profound lactic acidosis that typically accompanies seizures.

During chronic INH therapy, patients who are malnourished, pregnant, alcoholic, elderly, diabetic, or uremic may be at

particularly high risk for pyridoxine deficiency (5), which can lead to peripheral neuropathies, anemia, and a lowered seizure threshold. Pyridoxine depletion can also inhibit the activity of pyridoxine-dependent decarboxylases and transaminases (leading to decreased catecholamine synthesis), cytochrome P450 enzymes (leading to decreased drug metabolism), histaminase, and monoamine oxidase (MAO). Pyridoxine given as a supplement at 10 mg/d can avoid this deficiency.

CLINICAL PRESENTATION

Seizures may be seen after acute overdoses of INH as low as 35 mg/kg in adults. Severe toxicity occurs with ingestions of 5 to 7 g (80 to 150 mg/kg); but death has occurred after the ingestion of as little as 3 g. Although ingestions of >12 g in an adult have a high fatality rate, survival has been reported after the ingestion of as much as 25 g. Poisoning is associated with an INH serum concentration >30 μg/mL, although such laboratory assays for INH are not routinely available.

The initial symptoms of acute poisoning may occur as soon as 30 to 120 minutes after ingestion, and include nausea, vomiting, slurred speech, blurred vision, and disorientation. Anticholinergic signs (e.g., mydriasis, tachycardia, and urinary retention) and hyperreflexia or areflexia may also be prominent. In severe poisonings, seizures appear abruptly and precede the development of a profound metabolic acidosis and coma, the triad that forms the classic clinical picture. Patients with INH-induced seizures and severe acidosis can have full recovery after receiving pyridoxine. A 2-year-old girl who ingested 2 g of INH suffered status epilepticus and an arterial pH of 6.86, but survived without sequelae (6).

Multiple seizures over a short time are the hallmark of INH poisoning. Other symptoms and signs include confusion or irritability, hallucinations, stupor, ataxia, garbled speech, hyperpyrexia, nausea and vomiting, and respiratory depression. Laboratory findings include lactic acidosis, ketosis, hyperglycemia, an increased anion gap, hyper- or hypokalemia, peripheral blood

leukocytosis, CSF pleocytosis, and renal defects (e.g., glycosuria, keotnuria, albuminuria, and oliguria). An elevated creatine phosphokinase (CPK-MM fraction) level as a result of rhabdomyolysis may precede myoglobinuria and renal failure. In one series of INH poisoning, 60% had an elevated CPK-MM level, which correlates both with the dose of INH ingested and the frequency of seizures (7). An electroencephalogram (EEG) often demonstrates diffuse slowing or paroxysmal electrical activity compatible with subclinical seizures. The clinical course of the untreated patient with a massive INH overdose is often unremitting seizures, resulting in death from acidosis and cardiovascular and respiratory collapse. Survivors may suffer from persistent neuropsychological sequelae, including personality changes, poor memory, learning problems, and/or motor skills deficits (8).

Hepatotoxicity, with elevated liver enzyme levels, is relatively common among patients taking INH chronically. Such hepatotoxicity appears transient in most cases, even with continued use of the drug. Patients rarely develop acute liver necrosis, liver failure, and death. One study found 0.5% of patients treated with INH for 12 months were hospitalized for a hepatic event and estimated a rate of 0.1 cases of severe hepatitis per 100 person-years of INH use, with an increased risk among patients older than 65 years (9). Concomitant use of rifampin and INH in TB prophylaxis may increase the risk of an adverse hepatic event. A meta-analysis of 38 studies found that drug-metabolizing enzyme polymorphisms, including slow N-acetyl-transferase (NAT2), glutathione S-transferase (GSTM1), and CYP 2E*1 A, increased the risk of susceptibility to liver injury (10).

Toxic effects of chronic INH use also include euphoria, tinnitus, ataxia, impaired memory, encephalopathy, and optic neuritis. Progressive lethargy, garbled speech, confusion, and coma were described in a man who mistakenly took 1,200 mg of INH daily for 6 weeks (5).

Allergic manifestations, such as rashes, eosinophilia, vasculitis, arthralgias, and a positive antinuclear antibody test, have also been described. By inhibiting P450 series cytochromes, INH can interfere

with drug clearance and increase the toxicity of other drugs such as phenytoin, carbamazepine, theophylline, and warfarin. INH action as a weak monoamine oxidase inhibitor (MAOI) may result in symptoms (e.g., headache, flushing, nausea, vomiting, palpitations) in patients consuming foods containing tyramine or histamine (see Chapter 342). Hematologic abnormalities such as neutropenia, thrombocytopenia, sideroblastic anemia, pure red cell aplasia, and autoimmune hemolytic anemia have also been described in association with exposure to INH.

Patients with underlying hepatic disease or impaired renal function do not metabolize INH well, have a prolonged serum half-life, and are at greater risk for toxicity. Those with a preexisting seizure disorder are at higher risk for neurotoxic effects.

DIFFERENTIAL DIAGNOSIS

INH overdose should be strongly considered in the patient who presents with (1) seizures refractory to conventional anticonvulsants, and (2) a high anion-gap metabolic acidosis, especially in the context of depression, suicidal ideation, TB, and with access to INH. A diagnostic clue to INH poisoning is the prompt termination of seizure activity after the administration of IV pyridoxine.

Agents that can cause a clinical picture similar to that of INH overdose include salicylates, cyanide, carbon monoxide, other hydrazines (e.g., monomethylhydrazine-containing mushrooms), anticholinergics, and sympathomimetics. Other pharmacologic causes of status epilepticus include baclofen, carbamazepine, dimenhydrinate, and theophylline. Neurotoxins such as pesticides, camphor, lead, mercury, narcotics, strychnine, and tricyclic antidepressants should also be considered. Other medical conditions, such as bacterial meningitis with sepsis, diabetic ketoacidosis, uremia, other metabolic disorders, meningoencephalitis, and head trauma, should also be included in the differential of patients presenting with seizures, coma, and acidosis.

ED EVALUATION

The time, dose, and intent of ingestion; the time of onset, nature, and severity of symptoms; prehospital care; and medical and psychiatric history should be noted. The physical examination should focus on vital signs and neurologic status, including assessment for hyperreflexia, focal neurologic deficits, abnormal thought processes, and central nervous system (CNS) depression. Laboratory evaluation should include serum electrolytes, rapid bedside glucose, blood urea nitrogen, creatinine, and arterial pH, and blood gases. In severe or chronic cases, creatine kinase and liver function tests should be obtained. A chest radiograph can detect aspiration, and an electroencephalogram (EEG) may be helpful in patients with persistent coma.

KEY TESTING

- Arterial blood gases and lactic acid to detect metabolic acidosis with seizure
- Bedside blood glucose for coma or seizures
- Myoglobin and renal function tests for suspected rhabdomyolysis
- Complete blood count and electrolytes for general supportive care
- Liver function tests for suspected hepatitis in chronic users
- Head CT or MRI if other etiologies for seizures and coma are suspected

ED MANAGEMENT

Advanced life-support measures should be instituted as necessary. Pyridoxine (vitamin B_6) is the specific antidote for seizures. It should be given in gram-for-gram equivalency to the estimated total amount of INH ingested. If the total ingested dose of INH is unknown, 5 g of pyridoxine hydrochloride (IV injection solution available at a concentration of 100 mg/mL) can be given empirically by slow intravenous push (maximum 0.5 g/min), and repeated in 20 minutes if there is no clinical response. Typically, the seizures abate and the patient's level of consciousness slowly

improves. Diazepam (5 to 10 mg IV, preferably in a second IV site) may be used as an adjunct to control seizures and additional pyridoxine is sometimes necessary for the resolution of INH-induced coma.

The use of adequate doses of diazepam and pyridoxine has essentially eliminated the need for other treatment of INH overdose. Multiple large doses of pyridoxine should be avoided because chronic pyridoxine overdosing can cause a peripheral sensory neuropathy. Some commercially prepared IV pyridoxine may contain two different preservatives: chlorobutanol, which may cause mild sedation in high doses, and parabens, which has been implicated in hypersensitivity reactions.

Although severe metabolic acidosis should be treated with IV sodium bicarbonate, large doses are usually unnecessary, because the acidosis is mostly due to seizures and resolves shortly after seizures have been controlled. Diuresis is not of benefit. After stabilization, activated charcoal should be given in early-presenting, acute-overdose patients to prevent further absorption of INH or other co-ingestants.

CRITICAL INTERVENTIONS

- Administer IV pyridoxine hydrochloride (gram for gram of INH ingested), along with benzodiazepines, for INH-induced seizures
- Follow blood gas values and administer IV sodium bicarbonate to patients with severe acidemia, especially those with persistent seizures

DISPOSITION

Asymptomatic or mildly symptomatic patients can be observed in the emergency department for 6 hours before discharge, with suicidal evaluation as needed.

Moderately or severely symptomatic patients should be admitted to an intensive care unit. Patients with refractory seizures, severe respiratory depression, or renal failure should be transferred to a

hospital with intensive care capabilities if they are not locally available.

Common Pitfalls

- Failure to consider INH poisoning in patients with seizures refractory to conventional anticonvulsants and a high anion-gap metabolic acidosis.
- Failure to appreciate that asymptomatic patients may rapidly deteriorate.
- Failure to give pyridoxine early after a known overdose.
- Administration of excessive doses of sodium bicarbonate for the treatment of metabolic acidosis, which spontaneously resolves when convulsions cease.

CHAPTER 318 Organophosphate and Carbamate Insecticides

Christopher P. Holstege

Organophosphates (OPs) and carbamates are acetylcholinesterase (AChE) inhibitors which are generally encountered in emergency medicine following (1) pesticide poisoning and when (2) considered as a possible chemical weapon of mass casualties (see Chapter 350). World health statistics estimate that over 3 million serious pesticide poisonings occur worldwide, and such poisonings are the leading cause of suicide fatalities in the world (1). Thousands of patients exposed to OP- or carbamate-containing pesticides were reported to American poison centers in 2011 (2). Although exposures to these pesticides may be less common in urban regions, all emergency physicians must be familiar with treatment regimens because AChE inhibitors are also used as pharmaceuticals (e.g., topical malathion for the treatment of head lice; echothiophate, a long-acting topical miotic used to treat glaucoma; pyridostigmine and neostigmine, used for myasthenia gravis; and rivastigmine, galantamine, and donepezil for treatment of Alzheimer disease) and as chemical warfare agents (e.g., nerve agents soman, sarin, tabun, and VX).

Acetylcholine is a neurotransmitter found throughout the nervous system, including the central nervous system, the sympathetic and parasympathetic autonomic ganglia, the postganglionic parasympathetic nervous system, and at the skeletal muscle motor end plate (Fig. 318.1). Acetylcholine binds to and activates muscarinic and nicotinic receptors. Activating muscarinic receptors stimulates or inhibits cellular function at visceral smooth muscle,

cardiac muscle, and secretory glands. Nicotinic receptors are located at postsynaptic membranes in autonomic ganglia and at skeletal muscle motor end plates. The enzyme AChE regulates acetylcholine's activity within the synaptic cleft. As acetylcholine binds to AChE active site, the enzyme rapidly hydrolyzes acetylcholine to choline and acetic acid. These hydrolyzed products rapidly dissociate from AChE so that the enzyme is free to metabolize another molecule. OPs and carbamates inhibit AChE by binding at the enzyme's active site, the inhibited enzyme is unable to inactivate acetylcholine. As a result, excessive acetylcholine stimulation occurs. Carbamates form an unstable complex which spontaneously hydrolyzes within 24 to 48 hours, regenerating AChE and limiting the duration of toxicity. OPs differ from carbamates in that OPs undergo a second step: a portion of the bound OP is then cleaved producing a stable, covalent bond between the OP and AChE. This process is called *aging*. The time it takes for aging to occur depends upon the OP. AChE reactivaters, such as pralidoxime chloride, can remove the OP before aging occurs, and can restore enzyme function. However, once this aged covalent bond forms, AChE cannot be reactivated and activity is not restored until new enzyme is synthesized.

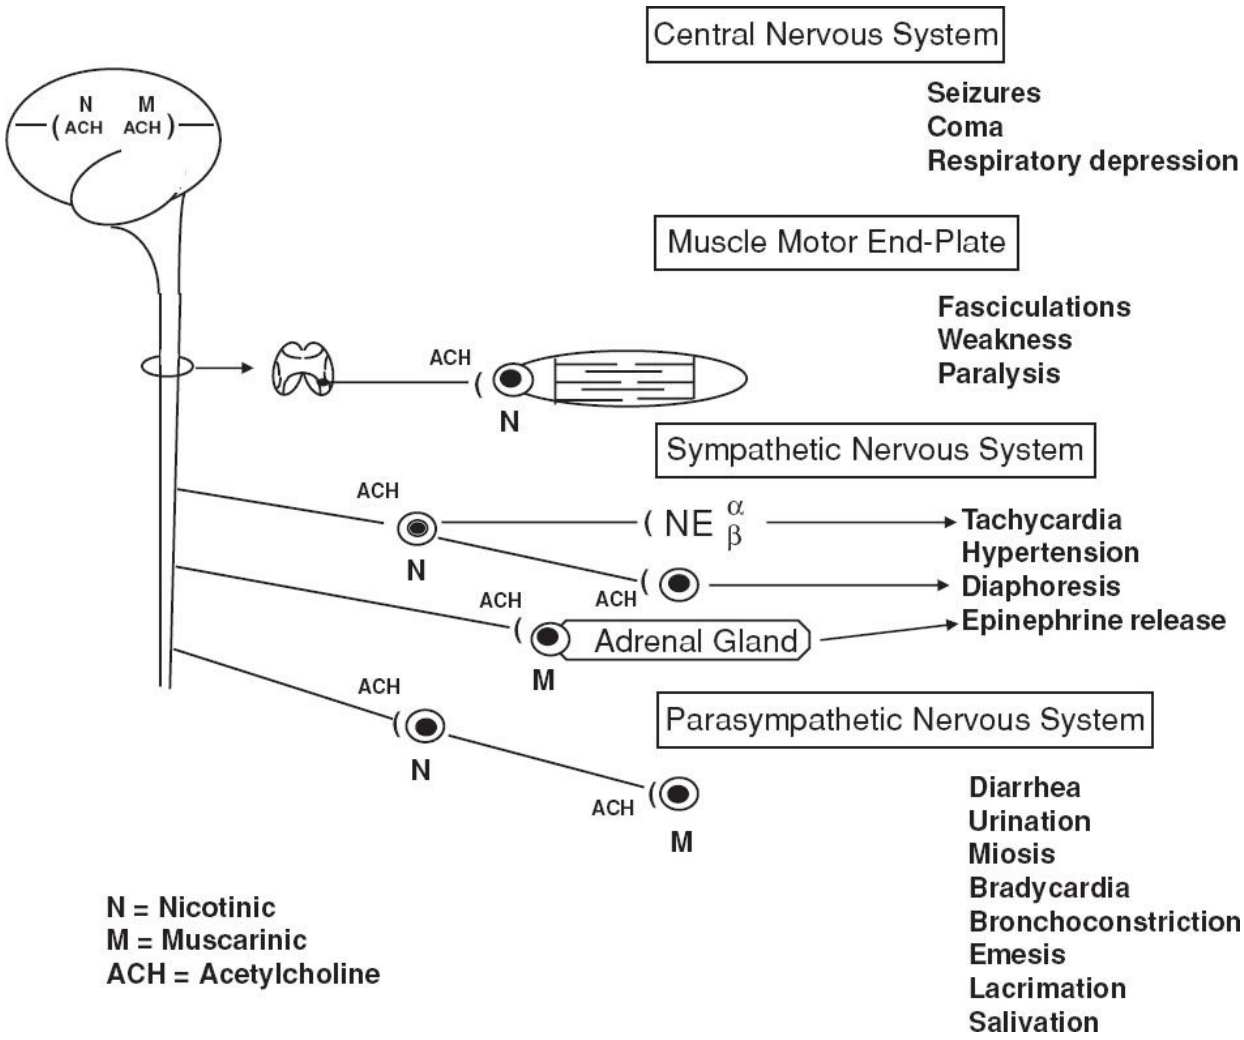

FIGURE 318.1 Clinical effects seen in organophosphate and carbamate poisoning caused by access of acetylcholine (Ach) in the central, autonomic, and peripheral nervous systems. M, muscarinic; N, nicotinic; NE, norepinephrine.

CLINICAL PRESENTATION

Acute Toxicity

The onset, severity, and clinical effects of OP and carbamate poisoning vary widely (Table 318.1) (3). Human exposures may occur inadvertently via inhalation or skin contact during pesticide application or via intentional ingestion. The type of agent, the dose, and the route of exposure are factors in determining the clinical effects. Depending on these variables, the progression of the signs

and symptoms can range from a gradual intoxication to cardiopulmonary collapse, seizures, and death within minutes.

TABLE 318.1
Signs and Symptoms of Acute Organophosphate and Carbamate Poisoning

Muscarinic Manifestations
Ophthalmic
Conjunctival injection, lacrimation, miosis, blurred vision, diminished visual acuity, ocular pain
Respiratory
Rhinorrhea, stridor, wheezing, cough, excessive sputum, chest tightness, dyspnea, apnea
Cardiovascular
Bradydysrhythmias, hypotension
Dermal
Flushing, diaphoresis, cyanosis
Gastrointestinal
Nausea, vomiting, salivation, diarrhea, abdominal cramping, tenesmus, fecal incontinence
Genitourinary
Frequency, urgency, incontinence
Nicotinic Manifestations
Cardiovascular
Tachydysrhythmias, hypertension
Striated Muscle
Fasciculations, twitching, cramping, weakness, paralysis
Central Nervous System Manifestations
Anxiety, restlessness, depression, confusion, ataxia, tremors, convulsions, coma, areflexia

Respiratory

The respiratory system effects of these agents tend to be dramatic and are often the major factor leading to the death of the victim. The development of respiratory failure is typically a triad of increased airway resistance, neuromuscular failure, and depression of the central respiratory centers. Weakness of the muscles of the tongue and pharynx can lead to upper airway obstruction. Laryngeal muscle

paralysis may occur resulting in vocal cord dysfunction and subsequent stridor. OP and carbamate can result in profuse watery nasal discharge, nasal hyperemia, and marked salivation. The lower respiratory tract may develop bronchorrhea and bronchoconstriction resulting in a prolonged expiratory phase, cough, and wheezing. As systemic absorption occurs, respiratory muscle weakness ensues and secretions cannot be cleared. Induced central respiratory center failure may contribute to the demise of the patient if intubation and ventilation is not initiated.

Central Nervous System

Cholinergic receptors are found throughout the central nervous system. Because of the widespread presence of these receptors, these agents can produce a large variation in neurological signs and symptoms. Headache, vertigo, paresthesias, anxiety, insomnia, depression, excessive dreaming, and emotional liability have all been reported following exposure. Centrally mediated respiratory failure can occur resulting in apnea. OP and carbamate are associated with seizure initiation, status epilepticus, seizure-related brain damage (SRBD), and subsequent death. Based on current evidence, the pathophysiologic progression of AChE inhibitor–induced seizures can be divided into three phases: (1) an early cholinergic phase that lasts from the time of exposure to approximately 5 minutes after seizure onset; (2) a transitional phase of progressively mixed cholinergic/noncholinergic modulation that begins more than 5 minutes after seizure onset and lasts until approximately 40 minutes; and finally (3) a predominantly noncholinergic phase beginning in approximately 40 minutes. These three phases are due to the cholinergic-induced seizure activity itself recruiting other excitatory neurotransmitter system (i.e., NMDA) that can eventually maintain the seizures independent of the initial cholinergic drive. The activation of NMDA ionic channels may lead to massive calcium fluxes into the postsynaptic cells resulting in cell degeneration and contributing to the profound SRBD.

Cardiovascular

The cardiovascular effects from OP and carbamate poisoning are variable and caused by either direct cholinergic effects at the heart or nicotinic effects at the autonomic ganglia. In addition, tachycardia and ventricular dysrhythmias are seen secondary to the hypoxia from respiratory failure. Cardiotoxicity resulting from AChE inhibitors has been divided into three phases. Initially, a period of intense sympathetic activity results in sinus tachydysrhythmias with or without hypertension. Patients may subsequently develop bradydysrhythmias, prolongation of the PR interval, atrioventricular blocks, and hypotension as parasympathetic tone predominates. The third phase occurs with QT prolongation and possible progression to polymorphous ventricular tachycardia (torsades de pointes). These phases can occur at any time in the poisoned victim and do not necessarily follow a specific progression.

Musculoskeletal

Somatic muscular activity is initiated at nicotinic receptors at motor end plates. With early or minimal exposure to these agents, symptoms may be vague and consist of muscular weakness and difficulty with ambulation. With increasing exposure, these agents resemble succinylcholine causing muscular fasciculations and subsequent paralysis. This is especially problematic as this paralysis may mask seizure activity.

Eye

These agents may rapidly penetrate the conjunctiva and stimulate muscarinic receptors resulting in lacrimation and miosis. Miosis can develop immediately after vapor exposure or after direct ocular contact with liquid. Following dermal absorption, miosis can be absent or delayed after other systemic signs and symptoms.

Dermal

The dermal sweat glands are innervated by sympathetic muscarinic receptors. When these receptors are stimulated, profuse sweating occurs.

Gastrointestinal and Genitourinary

Muscarinic receptor stimulation results in profuse watery salivation, nausea, vomiting, abdominal cramps, tenesmus, uncontrolled defecation, and involuntary urination.

Intermediate Syndrome

Intermediate syndrome was first described in 1987 and refers to the delayed development of muscle weakness without fasciculations or cholinergic features that occurs in OP-poisoned patients 24 to 96 hours after the acute poisoning. Patients who develop intermediate syndrome initially present with the classic cholinergic signs and symptoms of OP poisoning and have improvement following atropine and pralidoxime therapy. Relapse beginning approximately 48 hours later results in muscle weakness, cranial nerve palsies, and areflexia (4). The patient's mentation is not affected. These patients may progress to respiratory distress and paralysis lasting up to 2 weeks. Atropine and pralidoxime therapy are ineffective. The treatment of this syndrome is primarily supportive with intubation and ventilation as needed.

Delayed Peripheral Neuropathy

OP-induced delayed neuropathy (OPIDN) is associated with patients who developed significant OP toxicity and may occur 1 to 3 weeks following the initial poisoning (5). Typically, the patient will initially complain of weakness of the lower extremities, progressing to the upper extremities, ataxia, and potentially paralysis. Mild cases may recover over the ensuing months, whereas more severe cases will have persistent symptoms. OPIDN is partially caused by OP binding to neuropathy target esterase (NTE), an axonal membrane-bound target enzyme. Treatment of OPIDN is supportive and recovery may be incomplete.

Chronic Toxicity

Farmworkers who apply OPs and carbamate pesticides are at risk for ongoing low-level poisoning. These patients may present with no acute history of exposure and more subtle signs and symptoms. Symptoms may include blurred vision from miosis, and weakness as

well as the nausea, vomiting diarrhea, diaphoresis seen with acute exposure but in a more subdued or chronic course.

DIFFERENTIAL DIAGNOSIS

Similar cholinergic manifestations can be seen in patients poisoned with direct-acting cholinergic agonists such as bethanechol. Opioid and clonidine poisoning should be considered in patients who present with altered mental status and bradycardia, without other obvious signs of cholinergic toxicity. Lethargy and prominent sialorrhea or salivation may occur with certain antipsychotic agents, such as clozapine. Patients with nicotine poisoning as a result of ingestion of tobacco products or harvesting wet tobacco may have similar findings, including vomiting, diarrhea, fasciculations, weakness, altered mental status, and autonomic instability.

ED EVALUATION

The history should document the amount, time, and route of exposure and the identity of the agent involved if known. A regional poison center can assist in product identification and characterization of anticipated toxicity. Continuous cardiac monitoring and pulse oximetry are crucial because of potential tachy- and bradydysrhythmias, QT prolongation, torsade de pointes, and respiratory failure due to secretions and paralysis. The physical examination should focus on the vital signs and assessment of cardiopulmonary and neuromuscular function, especially motor strength and respiratory effort. Cholinergic signs, particularly respiratory tract secretions, should be noted. Blood gas analysis and forced vital capacity (FVC) will help quantify respiratory dysfunction. An ECG, chest radiograph, and routine blood workup, including complete blood count (CBC), electrolytes, blood urea nitrogen, creatinine, glucose, creatine phosphokinase, amylase, and liver function tests, should be obtained on symptomatic patients.

The diagnosis may be confirmed by documenting decreased plasma or red blood cell (RBC) cholinesterase activity. RBC cholinesterase activity is more specific, but plasma (pseudo) cholinesterase activity tests are less expensive and more widely

available. Although results are usually unavailable in a clinically relevant time frame, they can be helpful in cases in which the diagnosis is uncertain and in the evaluation of workers who apply pesticides with occupational exposures. Specimens should be obtained prior to the administration of pralidoxime, because this antidote can increase measured enzyme activity. Interpretation of results may be difficult as a result of the variability in baseline values, which are subject to a variety of factors.

KEY TESTING

- Pulse oximetry, FVC, blood gas, and chest radiograph to assess respiratory function
- ECG, CBC, serum electrolytes, renal and liver function should be obtained on symptomatic patients
- Plasma and RBC cholinesterase to confirm diagnosis in chronic exposure and to document the extent of poisoning

ED MANAGEMENT

The skin plays a protective role against the invasion of most chemicals. However, many of these agents rapidly penetrate this barrier. Patient decontamination is a fundamental aspect of the management to both terminate toxin exposure and prevent secondary contamination of staff. Decontamination begins with clothing removal and copious water irrigation. Staff should be protected with appropriate gowns, gloves, and masks (see Chapter 350).

Lifesaving treatment of severe poisoning should initially focus on a patent airway, adequate ventilation, and aggressive atropine administration. Early endotracheal intubation is crucial in the critically ill patient. If rapid sequence intubation is performed, succinylcholine should be avoided because it is metabolized by AChE and subsequent neuromuscular blockade would be prolonged (6). A nondepolarizing alternative such as rocuronium would be preferred. Initial attempts at ventilation may be difficult due to induced bronchoconstriction. Copious secretions in the upper and lower

airways must be suctioned. Intravenous access should be obtained immediately. Aggressive atropine use will improve ventilation by drying secretions and decreasing airways resistance. Because of a demonstrated dissociation between motor convulsant activity, or lack thereof, and EEG activity, continuous EEG monitoring should be performed.

Atropine is the initial drug of choice in the symptomatic victim (7). Atropine acts as a muscarinic receptor antagonist and blocks neuroeffector sites on smooth muscle, cardiac muscle, secretory gland cells, peripheral ganglia, and in the central nervous system. Atropine is therefore useful in alleviating bronchoconstriction and bronchorrhea, relieving tenesmus, abdominal cramps, nausea and vomiting, resolving bradydysrhythmias, and halting seizure activity. If IV access is not available, atropine can also be given by the intramuscular, or endotracheal, route. The dose varies with the type of exposure. For the mildly and moderately symptomatic patient, 2.0 mg for adults and 0.02 mg/kg for children (minimum of 0.1 mg) is administered every 5 minutes. In the severely poisoned patient, dosage will need to be given more rapidly and increased to very large amounts up to 40 mg or more in 24 hours. Tachycardia is an effect of poisoning and is not a contraindication to atropine administration. Drying of the respiratory secretions and resolution of bronchoconstriction are the therapeutic end points used to determine the appropriate dose of atropine. If bag-assisted ventilation is difficult or secretions continue, then the atropine dose must be increased. Atropine has no effect on the nicotinic receptors, autonomic ganglia, and the neuromuscular junction. Therefore, muscle weakness, fasciculations, tremors, and paralysis are not an indication for further atropine dosing. It does have a partial effect on the central nervous system and is helpful in resolving seizures. Miosis is a poor clinical sign to follow for guiding repeat doses of atropine. If the resolution of miosis is used as the end point of atropine dosing, an anticholinergic syndrome can develop.

Pralidoxime chloride (2-PAMCL, Protopam Chloride) reactivates AChE by removing the OP from the AChE leaving the regenerated enzyme able to once again metabolize acetylcholine. This

reactivation is clinically most apparent at the skeletal neuromuscular junctions, which is not improved with atropine with less activity at muscarinic sites. Pralidoxime must therefore be administered concurrently with adequate atropine doses. If pralidoxime is delayed, the process of aging will permanently bond the OP to the AChE active site and prevent pralidoxime from regenerating the AChE active site; therefore, the earlier the administration of pralidoxime, the greater the clinical effect. The recommended dose of pralidoxime is 1.0 g for adults or 15 to 25 mg/kg for children by intravenous route. Slow administration over 15 to 30 minutes can minimize side effects, which include hypertension, headache, blurred vision, epigastric discomfort, nausea, and vomiting. In order to achieve a steady state blood level of pralidoxime following loading, it has been recently recommended that a continuous IV infusion is safe and effective (8). Because carbamate poisoning does not induce aging and resolves spontaneously much quicker than OP poisoning, the use of pralidoxime for carbamates remains controversial. Pralidoxime use is probably not harmful for these patients and should be used if there is any doubt as to the pesticide involved.

OP and carbamate poisoning is associated with seizure initiation, status epilepticus, SRBD, and subsequent death. Effective and rapid management of seizures is critical. All centrally acting anticholinergic agents (i.e., atropine and scopolamine) can block onset or terminate seizures if given before or within 5 minutes of seizure onset, but are ineffective alone if treatment is delayed more than 40 minutes after seizure onset. Benzodiazepines (i.e., diazepam, midazolam, lorazepam) are effective in treating OP and carbamate agent–induced seizures. The combination of a benzodiazepine and an anticholinergic agent should be used to terminate seizures (9).

CRITICAL INTERVENTIONS

- Monitor oxygen saturation and evaluate airway patency.
- Monitor the cardiac rhythm and obtain an ECG.
- Administer atropine to patients with increased secretions and bronchospasm.

- Quickly work to stop associated seizures by giving atropine and benzodiazepines.
- Administer pralidoxime early to patients following symptomatic OP or unknown poisoning.

DISPOSITION

Patients with an unintentional exposure who remain asymptomatic after at least 6 hours of observation may be discharged to home with a family member. Those requiring treatment with atropine or pralidoxime and those with evolving toxicity should be admitted to an intensive care unit (ICU) for close observation and monitoring. Prophylactic intubation prior to initiating transport may be advisable in patients with borderline respiratory status.

Common Pitfalls

- Failure to decontaminate the skin of patients with dermal exposures.
- Failure to take appropriate precautions to prevent secondary exposure to healthcare workers.
- Failure to give atropine to patients with tachycardia who have excessive respiratory tract secretions or bronchospasm.
- Failure to appreciate that atropine should be titrated to drying of secretions rather than to heart rate or pupil size in doses that may exceed standard ACLS recommendations.
- Failure to treat symptomatic OP poisoned patients with pralidoxime to prevent "aging."
- Failure to appreciate that highly fat-soluble OPs may cause delayed, prolonged, or recurrent toxicity.

CHAPTER 319

Nicotine, Neonicotinioids, Pyrethrins, and Organochlorine Pesticides

William K. Chiang and Richard Y. Wang

Nicotine, the primary alkaloid of tobacco, is a naturally occurring pesticide obtained from *Nicotiana tabacum, N. rustica,* and other plants. It is also used in gum, nasal inhalers, and transdermal patches to aid in the cessation of smoking. Nicotine binds to nicotinic cholinergic (acetylcholine) receptors in the sympathetic and parasympathetic ganglion cells, neuromuscular junction, adrenal medulla, and the central nervous system (CNS). An initial transitory stimulation of nicotinic receptors is followed by a more persistent depression and paralysis as a result of desensitization (1). Clinical symptoms may reflect receptor stimulation, depression, or both.

Absorption occurs through intact skin, the gastrointestinal tract, and the respiratory tree. Nicotine has a pK_a of 8.5 and is not well absorbed in the acid milieu of the stomach but alkalinization markedly increases absorption. The volume of distribution is approximately 1 L/kg. Protein binding is 20%. Once absorbed, 80% to 90% of the chemical is detoxified into cotinine by the liver, and 20% is excreted unchanged by the kidneys. The elimination half-life is 0.8 hours in smokers and 1.3 hours in nonsmokers. Elimination is complete in about 16 hours.

Tobacco leaves contain 1% to 6% nicotine; a cigarette contains 15 to 20 mg of nicotine, with one-fourth remaining in the butt; snuff contains 4.6 to 15 mg of nicotine per gram of moist material; chewing tobacco contains 2.5 mg of nicotine per gram of dry material; a cigar contains 15 to 20 mg of nicotine. Nicotine gum contains 2 mg of nicotine buffered to a pH of 8.5 to enhance absorption. Transdermal nicotine patches release 7 to 21 mg of nicotine per day. However, the total nicotine content may range from 8.3 to 114 mg per patch. Nicotine nasal spray contains 10 mg of nicotine per milliliter. Electronic cigarette liquid refills may now be the most concentrated and potentially toxic nicotine products available. The nicotine concentration can be as high as 36 mg/mL, with bottle sizes exceeding 100 mL.

The toxic dose of nicotine varies. As little as 4 mg can cause symptoms; 40 to 60 mg is potentially fatal in an adult. In a small child, 1 mg of nicotine may cause symptoms (2). Ingestion of one cigarette, three cigarette butts, one cigar butt, or any amount of nicotine chewing gum or patch should be considered potentially toxic in a child.

Neonicotinoids, the only new major class of insecticides developed in the past four decades, are used for crop protection from piercing-sucking insects and for flea control in cats and dogs, and are available as a general insecticide for home use. Neonicotinoids are currently among the most widely used insecticides in the world. Neonicotinioids can be applied to seeds or soil; they are taken up by the plant and may offer protection from these insects for up to 40 days. Similar to nicotine, neonicotinoids act at the postsynaptic nicotinic receptors, where prolonged activation leads to desensitization and inactivation of the receptors, causing insect paralysis and death. Neonicotinoids are highly selective for insect nicotinic receptors (100 to 1,000 times more than vertebrates); making them relatively safe in human and animal exposures (3).

There are seven compounds available currently: acetamiprid, clothianidin, dinotefuran, imidacloprid, nitenpyram, thiacloprid, and thiamethoxam. Imidacloprid is the most commonly used compound. Because of concerns for their impacts on honey bee

population, on April 29, 2013, the European Union enacted a 2-year ban on the use of imidacloprid, clothianidin, and thiamethoxam on flowering plants until further scientific evidence is available. Neonicotinoids may also be toxic to birds and invertebrates.

Pyrethrins are naturally occurring insecticides extracted from chrysanthemum flowers; they are esters of pyrethric and chrysanthemic acid. *Pyrethroids* (e.g., permethrin, deltamethrin) are synthetic pyrethrins that are more stable (resist photolysis) in the natural environment and more potent against insects than pyrethrins. They can be separated into two classes based on their chemical structures: type II agents contain a cyano group at the alpha carbon (e.g., deltamethrin), and type I agents do not (e.g., permethrin).

Pyrethrins and pyrethroids are widely used as insect sprays because of their rapid incapacitating (knock-down) effects on insects. Most are formulated in petroleum distillates for spray applications. Synergists such as piperonyl butoxide, *N*-octyl-bicycloheptene dicarbonimide, and sesame oil derivatives are commonly added to inhibit the metabolism of pyrethrins and thus increase their efficiency. Pyrethrins and pyrethroids are also used to treat head lice and scabies and as insect repellents.

In insects, pyrethrins and pyrethroids rapidly cause death by paralyzing the nervous system. They inactivate sodium channels in nerve axons by binding and prolonging the open state. Other potential mechanisms of toxicity include the inhibition of adenosine triphosphatases and direct effects on membrane integrity. Type II pyrethroids also antagonize inhibitory chloride channels and alter calcium-ion transit, but this contribution to clinical toxicity is unclear (4). Because type II pyrethroids cause a longer opening of the sodium channels, they are generally more toxic than type I agents.

These compounds are rapidly degraded and are popular because they leave almost no residual in the environment. They are considered less toxic to mammals than any other major class of insecticides. Human toxicity is limited by a large first-pass effect by the liver, poor bioavailability, and rapid metabolic breakdown by

ester hydrolysis, followed by hepatic oxidation. Furthermore, the diversity of the α-subunits of the sodium channels in humans makes them less susceptible to pyrethroid toxicity than insects. Ingestion of amounts up to 5 mg/kg is unlikely to cause significant toxicity. The toxic oral dose is estimated to be >100 to 1,000 mg/kg, with a lethal dose estimated to be 10 to 100 g. Synergists also have low human toxicity.

Organochlorine pesticides are low-molecular-weight, fat-soluble aliphatic, aromatic, and complex hydrocarbons that contain chlorine (Table 319.1). The US Environmental Protection Agency canceled the use of many of these pesticides in the 1970s and 1980s because they persist in human tissue and the environment. In the years that followed this action, the remaining organochlorine pesticides were no longer registered for use or will be phased out by 2016 in the United States, although some of these insecticides can be available in other countries. An exception is heptachlor, which is still available as a second-line agent in the control of fire ants. *Lindane* (γ-hexachlorocyclohexane) is still available as a second-line agent in the control of human scabies. Enteral absorption of *organochlorines* is efficient and increased in the presence of animal or vegetable fat. To a lesser extent, they are absorbed across pulmonary membranes, but only 10% or less of a dermally applied dose (e.g., lindane) is absorbed. Different compounds exhibit different tissue-storage and hepatic elimination rates. Many (e.g., chlordane, dieldrin, and heptachlor) can induce hepatic enzymes.

TABLE 319.1
Chlorinated Hydrocarbon Insecticides

Insecticide	Brand/Trade Name
Aldrin	Aldrex, Aldrite, Drinox
Chlorobenzilate	Acaraben, Folbex, Kop-Mite
Chlordane	1068, Belt, Chlor Kill, Niran
Chlordecone	Depone, Tat Ant Trap
DDT	Anofex, Dinocide, Pentech
Dieldrin	Albit, Dorytox, Octalox
Endosulfan	Thiodan, Phaser, Thionex
Endrin	Agrine, Endrex, Hexadrin
Heptachlor	Velaicol, 53-CS-17
Lindane	Agrocide, Isotox, Kwell
Methoxychlor	DMDT, Marlate, Moxie
Mirex	Dechlorane, Ferriamide
Toxaphene	Alltox, Camphoclor, Motox

These compounds are excreted in the feces and can be found in breast milk. They are slowly cleared from the body because of their limited hepatic metabolism and preferential storage in the adipose tissue, which is poorly perfused by blood. It may require many months to years to eliminate mirex, chlordecone, DDT, and β-hexachlorocyclohexane; weeks to months for aldrin, dieldrin, heptachlor, and hexachlorobenzene; and hours to several days for endrin, chlordane, toxaphene, endosulfan, methoxychlor, and chlorobenzilate. Since the ban of these pesticides, the residual concentration of these organochlorines in Americans, especially in adipose tissue, has been decreasing.

Toxicity is due primarily to interference with the axonal transmission of nerve impulses. *Organochlorines* interfere with the normal flow of sodium and potassium ions across the axon membrane as nerve impulses pass. Unlike organophosphate insecticides, they do not depress cholinesterase enzymes. The acute toxic potential of organochlorines varies with the different compounds and their rates and routes of absorption. The products with the highest risk for toxicity include endrin, dieldrin, aldrin, chlordane, and toxaphene (5). Those with intermediate risk include chlordecone, endosulfan, heptachlor, mirex, and DDT. The products with the lowest risk for toxicity are methoxychlor, perthan, kelthane, chlorobenzilate, and hexachlorobenzene. Lindane is potentially toxic after multiple applications to the skin (6). Dermal

and inhalational exposures occur in workers who spray organochlorine pesticides or re-enter fields too soon after spraying. Oral exposure may result from eating or drinking contaminated food or water (7). The estimated oral lethal dose in adults is 3 to 7 g for aldrin, 6 g for chlordane (< 2 g can cause stupor and seizures), 1 to 5 g for dieldrin, and 10 to 30 g for lindane (as little as 1.6 g can cause seizures in children) (5).

CLINICAL PRESENTATION

Poisoning from *nicotine* can occur from (1) exposure to nicotine sulfate insecticides; (2) percutaneous absorption of nicotine in tobacco harvesters who pick and brush up against wet tobacco leaves (green tobacco sickness); (3) ingestion of tobacco products, such as cigarettes, snuff, chewing tobacco, and cigars; chewing or ingestion of nicotine chewing gum; and (4) improper use or ingestion of nicotine patches. Infants and young children are most susceptible to nicotine poisoning because of their small body size and the lack of tolerance. Similarly, tobacco harvesters are more likely to be symptomatic when they have the lowest nicotine tolerance, at the beginning of the harvesting season and workweek. Nonsmokers, lack of work experience, wet conditions, and the lack of protective clothing are risk factors for green tobacco sickness (8). Many nonsmoking tobacco harvesters resort to tobacco chewing as a means to develop nicotine tolerance. Overall, nicotine-related fatalities are rare because of its decreasing use as a pesticide.

Onset of toxicity is rapid and can be seen within 15 minutes of exposure. Initial signs and symptoms include nausea, vomiting, salivation, bronchorrhea, abdominal pain, and diarrhea from parasympathetic stimulation and tachycardia, hypertension, and diaphoresis as result of sympathetic and adrenal stimulation. Early CNS effects include dizziness, headache, confusion, agitation, incoordination, and seizures. Muscular fasciculations may result from neuromuscular junction stimulation.

As symptoms progress, hypotonia, muscle paralysis, respiratory failure, coma, bradycardia, and hypotension may ensue. Because of

both stimulatory and inhibitory effects on multiple systems, the signs and symptoms vary by the time, dose, and route of exposure. In severe cases, such as oral nicotine pesticide poisoning, the progression from stimulation to inhibition of the various systems may be rapid (2).

In mild nicotine poisoning, symptoms can last for several hours. In severe cases, clinical toxicity can endure for 18 to 24 hours or more. Severe cases involve seizures and coma within 30 minutes, with respiratory arrest and death within 1 hour or less, especially with concentrated nicotine products. Patients who survive the first 4 hours usually recover fully. Radiographic and electrocardiographic (ECG) findings are nonspecific. Nicotine can be detected in the urine by chromatographic drug assays.

The clinical presentations of *neonicotinoid* toxicity are similar to those of nicotine toxicity. Vomiting, oral ulcers, diaphoresis, bronchorrhea, mydriasis, bradycardia, tachycardia, and lethargy are common. In severe cases, the symptoms may progress to coma, hypotension, and respiratory failure. Oral mucosal corrosion may be secondary from the solvent carrier. The overall mortality reported for neonicotinoid poisoning is less than 3%, which is similar to that of pyrethroids but much lower than organophosphates and carbamates (9).

Direct toxicity from *pyrethrins* and *pyrethroids* is uncommon. When they occur, adverse effects are usually as a result of allergic hypersensitivity and include bronchospasm, vasomotor rhinitis, contact dermatitis, and, rarely anaphylaxis (10). After inhalation, the most common presentation is a stuffy nose with clear discharge and a “scratchy” throat. In rare cases, sudden bronchospasm, swelling of the laryngeal mucosa, and shock (anaphylaxis) can occur. Patients allergic to ragweed have a higher risk of developing allergic reactions to pyrethrins. Natural *pyrethrins* are more likely than synthetic *pyrethroids* to cause these reactions.

Direct dermal exposure to pyrethrins can produce a contact dermatitis consisting of redness, blisters, burning, stinging, and numbness. Transient paresthesia is related to the direct effects on cutaneous nerve endings and more commonly associated with type

II pyrethroids. Ocular exposure to hydrocarbon propellants can cause eye irritation and corneal abrasions. Large exposures to type II pyrethroids can cause tremors, salivation, paresthesia, ataxia, choreoathetosis, and seizures. Similar exposure to type I agents can result in tremors, agitation, and hyperthermia.

The onset of symptoms after exposure to *organochlorine* insecticides may vary from minutes to hours, depending on the route and method of exposure and the physicochemical properties of the agent (7). Nausea, vomiting, and diarrhea can occur as soon as 45 minutes after acute ingestion. Initial CNS effects include apprehension, headache, dizziness, tremors, ataxia, and disorientation. Stupor, coma, and seizures with respiratory depression may be seen in severe cases. Dysrhythmias may result from increased myocardial sensitivity to catecholamines.

Aspiration of formulations containing a petroleum distillate can result in a chemical pneumonitis. CNS toxicity, including seizures, can also occur in children after prolonged or excessive topical *lindane* exposures during the treatment of lice or scabies (6). In severe cases, potential complications include lactic acidosis, rhabdomyolysis, and disseminated intravascular coagulation.

Chronic exposure to *organochlorines* in workers can cause neurologic manifestations, including paresthesia, tremors, opsoclonus, and seizures. Extensive or prolonged dermal contact can result in skin irritation in the occupational setting. Chronic ingestion of hexachlorobenzene has been associated with cutaneous porphyria.

DIFFERENTIAL DIAGNOSIS

Without a history of exposure, there are no pathognomonic signs of nicotine and neonicotinoid poisoning. It could be confused with acetylcholinesterase inhibitor poisoning, such as OP or carbamate insecticides, and carbamate drugs (edrophonium, physostigmine). In nicotine and neonicotinoid poisoning, however, there is no depression of the red blood cell cholinesterase.

Direct-acting cholinomimetic agents such as bethanechol, carbachol, methacholine, and pilocarpine can also produce cholinergic effects similar to those of nicotine. However, because these agents have minimal effects on nicotinic receptors (except for carbachol), they produce minimal or no sympathetic or muscular symptoms. Central and peripheral sympatholytics (α-adrenergic and β-adrenergic receptor blockers, clonidine, guanabenz, topical decongestant imidazoline derivatives, and calcium blockers) can mimic the later stages of nicotine poisoning. These agents will not produce any muscarinic symptoms or neuromuscular weakness. Tree tobacco (*Nicotiana glauca*), native to the temperate regions of America, contains the alkaloid anabasine, an isomer of nicotine that can cause similar symptoms. Other substances to consider are the insect-repellent diethyltoluamide, Veratrum and sabadilla plants, Clitocybe and Inocybe mushrooms, and poison hemlock (*Conium maculatum*).

Pyrethrins and pyrethroids should be included in the differential diagnosis of patients who present with an apparent hypersensitivity reaction of the skin or respiratory system when exposed to flora, insecticides, or insect bites. Because almost all of the insecticides containing these compounds are in a hydrocarbon base, the risk of hydrocarbon pneumonitis must be considered in humans ingesting these products.

Acute organochlorine insecticide poisoning must be distinguished from any condition that produces “gastroenteritis” with an altered mental status, especially ataxia, tremors, and seizures. CNS disease, drug withdrawal, stimulant intoxication (e.g., from sympathomimetics, xanthenes, anticholinergics, hallucinogens, and isoniazid), and infectious etiologies should be considered.

ED EVALUATION

The history should document the time, agent, dose, route, intent, and duration of exposure and the nature and course of symptoms. The physical examination should pay particular attention to cardiovascular, respiratory, and neurologic function. Patients with

vital sign abnormalities should have an ECG. Symptomatic patients should have cardiac and oxygen saturation monitoring. Chest radiographs, oxygen saturation measurement or arterial blood gas analysis, and pulmonary function tests can assess respiratory function and possible aspiration in patients with wheezing, dyspnea, cough, and fever. Blood chemistries and hematologic analysis should be obtained based on clinical severity.

No specific laboratory tests are diagnostic. The presence of nicotine in the urine of a nonsmoker is supportive. Plasma nicotine levels are not useful. Organochlorine insecticides can be measured in the serum by using gas chromatography/mass spectrometry, but levels are not useful for clinical management. However, in a patient with a suspicious exposure for DDT, a high DDT to DDE ratio confirms that the exposure was recent.

KEY TESTING

- There are no specific laboratory tests.
- ECG and CXR should be obtained in symptomatic patients.
- Pesticide levels can be obtained but do not aid clinical management.

ED MANAGEMENT

GI, skin, and eye decontamination should be performed. Activated charcoal (AC) is the preferred method for early GI decontamination. Pyrethrins and pyrethroids are lipophilic, so milk, cream, or substances that contain animal or vegetable fats should not be administered. Except for recent ingestion (<1 hour) of large quantities of a nicotine or neonicotinoid pesticides, gastric aspiration or lavage would not likely provide additional benefit. Seizures and coma can occur rapidly, and emesis increases the risk of aspiration. If present, all transdermal patches should be removed.

Exposed skin areas should be washed with soap and water. Exposed eyes should be irrigated with copious amounts of water for 15 minutes. Powder contaminating the skin should first be

vacuumed off. Contaminated clothing should be removed, and the skin, hair, and nails scrubbed.

The patient should be closely monitored for the first few hours after exposure. Supportive care, including oxygen, endotracheal intubation, and assisted ventilation, should be instituted as necessary. Intravenous access and cardiac monitoring are indicated for all but mild intoxications. Seizures should be treated with intravenous benzodiazepines such as diazepam (for adults, 5 to 10 mg initially, repeated every 5 to 10 minutes as necessary, up to 30 mg; for children, 0.25 to 0.4 mg/kg per dose) or lorazepam (0.05 to 0.1 mg/kg, which may be repeated twice every 15 minutes as necessary). If seizures cannot be controlled with diazepam or lorazepam, a barbiturate (such as phenobarbital or pentobarbital) or propofol may be given. Phenytoin is not likely to be effective and may actually increase the incidence of seizures in organochlorine poisoning.

Excess parasympathetic stimulation (e.g., marked bronchial secretions) from nicotine and type II pyrethroids can be controlled by atropine (adults, 0.5 to 1 mg intravenously, repeated every 5 minutes as necessary; children, 0.01 to 0.02 mg/kg intravenously). Oxygen and ventilation may be necessary. Hypotension should be treated with intravenous fluids; dopamine or norepinephrine may be added. Mecamylamine (Inversine), an older antihypertensive agent, is a specific nicotine antagonist but is available only in tablets, and is not practical in a patient who is vomiting, seizing, or hypotensive.

Anaphylaxis should be treated as usual (see Chapter 175). The management of hydrocarbon aspiration is supportive (see Chapter 331). Respiratory distress as a result of bronchospasm is managed with inhaled bronchodilators and humidified oxygen. Parenteral administration of adrenergic amines (e.g., epinephrine) is not recommended in organochlorine insecticide poisoning because myocardial irritability may be enhanced. Contact dermatitis may be treated with topical corticosteroids.

Because organochlorine compounds have an extensive enterohepatic recirculation, multiple-dose activated charcoal (MDAC) is recommended to enhance their elimination. Multiple

doses of cholestyramine resin are also effective but is less well tolerated than charcoal. Extracorporeal procedures are not effective in enhancing organochlorine elimination. MDAC, hemodialysis, and hemoperfusion have not been evaluated in nicotine, neonicotinoid, and pyrethrin poisoning.

CRITICAL INTERVENTIONS

- Establish IV access and institute cardiac monitoring.
- Secure the airway and assist ventilation as necessary in patients with neurotoxicity.
- Decontaminate dermal exposures with clothing removal and soap with copious water.
- Administer benzodiazepines and, if necessary, barbiturates and propofol for seizures.
- Administer atropine to treat excess parasympathetic stimulation.
- Treat hypersensitivity reactions to pyrethrins or pyrethroids similarly as in any other allergic reaction.
- Administer MDAC for organochlorine insecticide ingestions.

DISPOSITION

Patients who remain or become asymptomatic after a 6-hour period of observation after an acute exposure may be discharged with appropriate follow-up. Patients with mild allergic reactions can be discharged after treatment. Chronic organochlorine insecticide exposures can generally be treated as outpatients. All others should be admitted to the hospital, observed, and treated supportively. Because the cardiorespiratory system requires monitoring, intensive care unit admission is advised. If such facilities are unavailable, the patient should be transferred with advanced life-support measures and anticonvulsants available. If necessary, consultation can be obtained from a regional poison center (1-800-222-1222) or the National Pesticide Telecommunications Network (1-800-858-7378). If the exposure occurred at the workplace, the proper health agency should be notified to prevent further occurrences.

Common Pitfalls

- Failure to discover a nicotine patch unintentionally stuck to the skin of an infant or toddler with altered mental status who was not completely undressed.
- Failure to properly decontaminate patients with dermal exposures.
- Failure to diagnose and treat respiratory failure, the primary cause of death in nicotine and neonicotinoid poisoning.
- Failure to appreciate that antacids for GI symptoms may increase the absorption of ingested nicotine.
- Failure to consider the possibility of aspiration (hydrocarbon) pneumonitis in patients with respiratory symptoms after ingestion.
- Mistaking organochlorine insecticides for OP insecticides (and vice versa), resulting in incorrect treatment.

The findings and conclusions in this chapter are those of the authors and do not necessarily represent the views of the Centers for Disease Control and Prevention.

CHAPTER 320 Rodenticides

Suzanne K. Bentley and Richard D. Shih

Rodenticides, "rat poisons," are a large, disparate group of chemical compounds; their only commonality is that they are utilized to kill rats, mice, squirrels, and other small animals. They have varied mechanisms of action, toxicities, and times of onset. Fortunately, medically significant, unintentional rodenticide exposures are uncommon in the United States due to legislation regulating their sale and use. Most exposures are in children, especially those younger than 6 years old, accidental, involve an oral anticoagulant, and result in minimal or no toxicity. Adults with intentional ingestions, however, often develop significant morbidity and mortality.

Oral anticoagulants are the most commonly used rodenticides in the United States (1). Toxicity results from inhibition of the cyclic regeneration of vitamin K, a cofactor required for the activation of coagulation factors II, VII, IX, and X. Although vitamin K depletion occurs almost immediately, no anticoagulant effect is seen until the activity of at least one clotting factor is diminished to below 25% of normal (2). Because factor VII has the shortest half-life among the clotting factors affected ($t_{½}$ = 5 hours), at least three half-lives (15 hours) are usually required before any toxicity is manifested.

Conventional anticoagulant rodenticides contain low concentrations of warfarin (0.025% to 0.05% or 100 to 200 mg in a pound of bait). These products were designed to kill rodents who ingest this bait daily over a period of several weeks. Their widespread use resulted in rodents' becoming resistant to their effects. Thus, higher-potency agents (superwarfarins) were

developed. These cause prolonged coagulopathy with ingestions of even smaller doses.

Other less commonly utilized rodenticides include arsenic compounds, organophosphates (OP), red squill, sodium monofluoroacetate, strychnine, tetramine, thallium, vacor, cholecalciferol, yellow phosphorus, and zinc phosphide. Arsenic compounds, used more commonly in the past, were a leading cause of rodenticide-related deaths in the 1950s and 1960s. Professional exterminators may still have access to arsenicals, depending on local laws. Arsenic causes rapid onset of toxicity by combining with and inhibiting sulfhydryl-containing enzymes (see Chapter 326).

Cholinesterase inhibitors include OP and carbamate compounds, which are used primarily as insecticides (see Chapter 318). Although they are not sanctioned for use as rodenticides in the United States, foreign manufacturers may use them for this purpose, and the probability of these products reaching the United States continues as international travel and immigration continues to increase. A case series from the New York Poison Control Center of 35 patients with exposure to "Tres Pasitos" identified aldicarb, an extremely potent carbamate-type cholinesterase inhibitor that is not licensed for rodenticide use in this country. It highlights an ongoing epidemic of acute poisoning, primarily in Dominican descendants living in New York City, following illicit sale of undocumented compounds, and its availability poses a substantial public health threat (3).

Red squill is a cardiac glycoside derived from the plant *Urginea maritima.* Its toxicity relates to its ability to block sodium–potassium-ATPase similar to digoxin. This toxin is poorly absorbed in humans because of its potent emetic effects. In rodents, however, whose vomiting mechanism is less well developed, the toxin is fairly effective.

Sodium monofluoroacetate (SMFA) is a white, odorless, tasteless, water-soluble salt typically available as a powder. Once absorbed, SMFA (and the closely related compound fluoroacetamide) rapidly enters the Krebs cycle, in which it is converted to fluorocitric acid, which inhibits the Krebs cycle, blocking aerobic metabolism (4).

Strychnine, a natural alkaloid derived from the native Indian tree *Strychnos nux-vomica,* has been used as a rodenticide since the 1600s. It is a potent neurotoxin that acts by competitively inhibiting glycine at postsynaptic receptors. Because glycine is the predominant inhibitory neurotransmitter in the spinal cord, its inhibition results in muscular rigidity and hyperexcitability (5).

Tetramine is not sanctioned for use as a rodenticide in the United States. However, it is utilized for this purpose in mainland China with sporadic cases reported in the United States and Hong Kong. Tetramine is an extremely potent picrotoxin-like agent that blocks γ-aminobutyric acid receptors in the brain causing prolonged convulsions leading to multi-organ failure and imminent death (6).

Thallium is an odorless, tasteless, highly toxic heavy metal. Although it can penetrate intact skin, it is more readily absorbed when ingested. Thallium, like arsenic, binds to and inhibits sulfhydryl-containing enzymes. Unlike arsenic, however, it preferentially affects mitochondria (7).

When first introduced, *Vacor* was thought to have no human toxicity. After numerous cases of severe poisoning occurred, it was voluntarily withdrawn from the market in 1979. Vacor is selectively toxic to pancreatic β-islet cells, producing a chemically induced form of insulin-dependent diabetes mellitus. The exact mechanism for the islet cell destruction is unclear, but it may be as a result of Vacor's ability to deplete β-islet cells of nicotinamide adenine dinucleotide (NAD) (8).

CLINICAL PRESENTATION

The majority of oral anticoagulant exposures involve unintentional ingestions in children younger than 6 years of age. Acute, single, unintentional ingestions of conventional anticoagulants are unlikely to cause toxicity because of their low warfarin concentrations. Similarly, children who unintentionally ingest superwarfarins in a single dose are unlikely to develop toxicity. In contrast, adults with intentional ingestions or children with repeated ingestions often develop a coagulopathy within 24 or, at the latest, 48 hours. If this goes untreated, bleeding complications may develop. The most

common sites of bleeding are the gastrointestinal (GI) and genitourinary tracts (1).

The other rodenticide agents are much less common and their clinical presentations are listed in Table 320.1.

TABLE 320.1
Rodenticide by Unique Identifier, Clinical Presentation, and Time of Symptom Onset

Rodenticide	Unique Identifier	Clinical Presentation	Onset
Arsenic	Garlic-like odor in breath	Severe vomiting, bloody diarrhea, dehydration, ventricular dysrhythmias, CNS and CV depression, CV collapse, late-onset neuropathies (see Chapter 326)	Early
Cholinesterase inhibitors	Cholinergic syndrome	Oral, dermal, or inhalation route of exposure. Salivation, lacrimation, defecation, urination, vomiting, GI cramping and/or pain, mental status change, seizures, muscle fasciculations, or weakness (see Chapter 318)	Early
Red squill	Similar to cardiac glycoside such as digoxin	Myocardial irritation, dysrhythmias, hyperkalemia, GI symptoms, blurred vision (see Chapter 325)	Early
SMFA toxicity	Severe lactic acidosis	Ingestion is most common exposure route in severe poisoning; initial symptoms: nausea and apprehension, followed by lactic acidosis, pulmonary edema, coma, hypokalemia, hypocalcemia, seizures, dysrhythmias; poor prognosis with early-onset acidosis and secondary renal insufficiency (4)	Early
Strychnine	Risus sardonicus (facial spasms), mistaken for having "seizures"	Decorticate posturing, opisthotonos, "seizure" with normal mental status; prolonged muscle spasm leads to hyperthermia, rhabdomyolysis, lactic acidosis, and death often from respiratory dysfunction; similar presentation to tetanus (5)	Early
Tetramine	Rapid onset seizures	Status epilepticus, high fatality rate, residual neurological injury in survivors (6)	Early
Thallium	12 to 24 hours delay in onset, extremely painful extremity paresthesias	Initially, GI symptoms predominate; in severe cases, dysrhythmias develop +/– death; survival characterized by period of alopecia and neurological findings (neuropathies, paresis, ataxia, choreiform movements, optic nerve atrophy) (7)	Early or late
Vacor	Severe diabetic ketoacidosis (DKA), odor of peanuts	Rapid loss of glucose control (destroys pancreatic beta cells), acute pancreatitis, autonomic instability, peripheral paresthesias, esophageal or GI perforation; survivors characterized as brittle insulin-dependent diabetics, often with accelerated microvascular diabetic disease (8)	Late
α-Naphthylthiourea	Acute lung injury	Hypothermia, pulmonary edema	Early
Barium	Neuromuscular blockage	GI symptoms, headache, long QTc, cardiac and pulmonary failure	Early
Bromethalin	Focal motor seizures	Muscle tremors, ataxia, myoclonic jerks	Early
Yellow phosphorus	Skin and GI burns	Dysrhythmias, coma, seizure, cardiac arrest	Early
Oral anticoagulants	Hemorrhage	Elevated INR, death from hemorrhage (1,9)	Late
Cholecalciferol	Hypercalcemia	Lethargy, renal failure, weakness	Late

DIFFERENTIAL DIAGNOSIS

Exposure to an unknown rodenticide is common. In such cases, it is useful to classify rodenticides clinically, based on their time of onset and symptoms (see Table 320.1). When the time of symptom onset and the nature of the symptoms are considered, a presumptive diagnosis can be established. Patients exposed to rodenticides with a rapid onset of action can be expected to manifest symptoms within 6 hours of ingestion. Those with exposure to rodenticides that have a delayed onset typically manifest symptoms beginning 12 hours or more after ingestion.

When symptoms are rapid in onset, cholinergic findings suggest OP poisoning; muscular hyperactivity suggests strychnine; seizures, coma, and metabolic acidosis suggest SMFA or tetramine; severe GI symptoms suggest arsenic; hyperglycemia suggests Vacor; and GI symptoms with cardiac dysrhythmias suggest red squill.

Lack of symptoms during the first 6 hours after exposure to an unknown rodenticide suggests either a nontoxic exposure to a rapidly acting agent or a potentially toxic exposure to a rodenticide with a delayed onset of toxicity (e.g., an oral anticoagulant or thallium). The most common cause of delayed symptoms from rodenticide poisoning is superwarfarin anticoagulants.

An additional diagnostic clue for suspected rodenticide exposure is odor. Arsenic and yellow phosphorus smell like garlic. Vacor smells like peanuts, and patients with Vacor-induced diabetic ketoacidosis (DKA) may have the fruity odor of ketones on their breath.

ED EVALUATION

Patient history is critical and must include the amount ingested, the time of ingestion, and the identity of the product involved. The most useful piece of information is the precise name and manufacturer of the ingested product.

A family member should be asked to return to home and try to get this information if the product is not brought along with the patient. The actual container or list of active ingredients is preferred over the commercial name, because many commercial names have been used for several products with different active ingredients. If product identity is unavailable, clinical manifestations may suggest the offending agent (see Table 320.1, Unique Identifiers).

While the diagnostic evaluation is proceeding, consideration and institution of therapy must occur simultaneously, as many of these poisons cause rapid and potentially fatal toxicity. The initial assessment should address the airway, breathing, and circulation. Strychnine may cause respiratory failure secondary to tonic muscle contractions and inability to ventilate. Toxicity from several of the other rodenticides can evolve rapidly to produce CV collapse.

Vital signs should be obtained immediately and reassessed frequently. Life-threatening hyperthermia may occur as a result of increased muscle activity with strychnine poisoning. Clinical clues include specific odors associated with the different toxins and the quality and amount of emesis or diarrhea. Signs of bleeding in the GI or genitourinary tract may indicate oral anticoagulant exposure, although these findings would be delayed in onset.

Laboratory testing should be based on the history and physical exam, identity of product ingested, and unique identifying aspects of clinical manifestation, when present. Blood chemistries and a complete blood count are rarely useful in the absence of clinical findings. A low serum bicarbonate concentration might be found in symptomatic patients with SMFA, strychnine, tetramine, or Vacor exposures. An elevated serum glucose level, especially in association with a metabolic acidosis, suggests Vacor-induced DKA. A prothrombin time/international ratio (PT or INR) should be obtained in patients with remote (>24 hours) or repeated anticoagulant ingestions. If obtained shortly after a single ingestion, the PT/INR should be normal, and measurement is not helpful. In chronic anticoagulant exposures or in patients who present with active bleeding several days after exposure, an elevated PT/INR may be diagnostic.

The need for radiographic assessment should be guided by the toxin involved. Exposure to agents that produce pulmonary toxicity mandates a chest radiograph. Abdominal radiography may help detect opacities in the gut in recent ingestions of the metal toxins (arsenic or thallium). If a sample of an unidentified rodenticide is obtained, taking a radiograph of it may help determine its heavy-metal content (7).

KEY TESTING

- Testing is based on the compound
- PT/INR is not necessary after a single acute anticoagulant ingestion
- PT/INR is helpful several days after anticoagulant ingestion or in patients with bleeding

ED MANAGEMENT

Treatment begins with stabilization of vital signs; advanced life-support measures are instituted, as appropriate. Once the patient is stable, gastric decontamination should be considered for recent ingestions. For the asymptomatic patient who has ingested an unknown rodenticide, activated charcoal is the preferred method. Orogastric lavage may be used in any patient giving a history of recent ingestion (within 2 to 4 hours) of a highly toxic rodenticide such as arsenic, superwarfarin anticoagulants, SMFA, strychnine, tetramine, thallium, or Vacor. Although little data exist on the efficacy of orogastric lavage, this intervention seems justified given the severe potential toxicity and lack of effective antidotes for most of the compounds in this group. Activated charcoal should be given after lavage.

Management of asymptomatic patients with unknown ingestions involves daily follow-up with PT/INR testing to see whether anticoagulant toxicity has manifested. A normal PT/INR at 48 hours after ingestion excludes significant anticoagulant toxicity (9). Prophylactic treatment with vitamin K_1 is not recommended when there is a normal PT/INR. It is important to note that vitamin K_1 will not prevent toxicity, which might last for a month, and thus only delays detection (9).

The treatment of *tetramine* poisoning is entirely supportive. Management of *arsenic* poisoning also includes chelation therapy (see Chapter 326) and that for cholinesterase inhibitor poisoning also includes atropine and pralidoxime (see Chapter 318). *Red squill* poisoning is treated the same as cardiac glycoside toxicity from other causes; digoxin-specific Fab fragments can be used (see Chapter 325).

Coagulopathy from *superwarfarins* without significant bleeding is treated with vitamin K_1. It is important to note that not all vitamin K preparations are effective; phytonadione (AquaMephyton, vitamin K_1) is the only antidote recommended for this purpose. The dose and the duration of treatment vary with the type and amount of

anticoagulant ingested and the patient's rate of toxin metabolism. Obtaining serial levels of the toxin to determine its elimination curve may help predict the duration of treatment; however, in practice, treatment is continued until the coagulopathy is corrected. Doses of up to 100 mg/d of vitamin K_1 for as long as 10 months have been necessary for superwarfarin poisoning (9). In patients with life-threatening bleeding, fresh-frozen plasma, recombinant activated factor VII, and/or plasminogen complex concentrates should be administered. Little data are available comparing efficacy of these different agents. Use of one agent over another or in combination should be made on a case by case basis (10).

Suggested antidotal treatments for *SMFA* toxicity include glycerol monoacetate or ethanol, although neither approach has been well studied. Glycerol monoacetate is thought to work by bypassing the site of blockage in the Krebs cycle. Ethanol may inhibit the conversion of *SMFA* to fluorocitrate and allow for excretion of the nontoxic parent compound (4). Given the relative safety of ethanol administration and the severe toxicity of SMFA, treatment with ethanol appears warranted.

Treatment of muscle overactivity, the main problem that leads to the life-threatening complications in *strychnine* poisoning, includes high doses of benzodiazepines and, if necessary, neuromuscular paralysis. If the patient is hyperthermic, aggressive rapid cooling (see Chapter 360, "Heat-Related Illness") is critical.

Patients with *thallium* poisoning should be treated with prussian blue (ferric ferrocyanide) (7) and multiple-dose activated charcoal, with the addition of either hemodialysis or hemoperfusion in life-threatening cases. Prussian blue is given at a dose of 250 mg/kg/d with a cathartic in divided doses.

Niacinamide (nicotinamide) is an effective antidote for *Vacor* in experimental animals. In these studies the earlier the antidote was given after exposure, the better the outcome. Niacin is not an effective substitute. Niacinamide (500 mg initially, followed by 100 to 200 mg every 4 hours for 2 days) is recommended for all patients with Vacor ingestion. Because an intravenous formulation is not

available, it should be given orally. Patients who develop DKA are managed like other diabetic patients.

CRITICAL INTERVENTIONS

- Positively identify the rodenticide's active ingredients
- Arrange for a 48-hour follow-up PT/INR for asymptomatic superwarfarin or unknown rodenticide exposures

DISPOSITION

For symptomatic patients exposed to a highly toxic rodenticide such as arsenic, superwarfarin anticoagulants, sodium monofluoracetate, strychnine, tetramine, thallium, or Vacor, hospital admission to a monitored setting is warranted. Because of the relative rarity of these exposures, consultation with a medical toxicologist or a regional poison center is recommended early in the presentation.

Patients with unintentional exposures who remain asymptomatic after 6 hours of observation can be discharged. For patients exposed to superwarfarin or long-acting oral anticoagulants, follow-up coagulation studies are needed at 48 hours after ingestion. These studies may be performed in the outpatient setting for patients with unintentional ingestions, provided there is adequate family and social support. All other patients, including those with intentional ingestions, are best managed as inpatients.

Common Pitfalls

- Failure to obtain a sample or container to identify the ingested agent.
- Misidentification of the rodenticide because an identical or similar brand name or market name is used for more than one agent.
- Failure to consider ingestion of an agent with delayed onset of action in a patient with an unknown rodenticide exposure who remains asymptomatic after a period of observation.
- Using the wrong type of vitamin K to treat oral anticoagulant toxicity.
- Beginning vitamin K treatment when the PT/INR is normal.

PART 6 • CARDIOVASCULAR DRUGS

CHAPTER 321

Antidysrhythmic Drugs and Local Anesthetics

S. Rutherfoord Rose and Paul E. Stromberg

This chapter focuses on Vaughan–Williams class I and class III antidysrhythmic agents (Table 321.1) and local anesthetics, whose mechanism and toxic effects are similar to that of lidocaine. Other antidysrhythmics are discussed elsewhere. See Chapter 323 (Vaughan–Williams class II) and Chapter 324 (Vaughan–Williams class IV).

TABLE 321.1
Classification of Antidysrhythmic Drugs

Class	Actions	Examples
I	Sodium channel inhibition	
A	Increased APD	Quinidine, disopyramide, procainamide
	Increased ERP	
	Slowed conduction	
B	Little/no decrease in APD	Lidocaine, tocainide, phenytoin, mexiletine
	Increased ERP in diseased tissue	
	May increase conduction velocity	
C	Variable effect on APD	Encainide, flecainide, propafenone
	Small increase in ERP	
	Markedly slowed conduction	
II	β-Adrenergic blockade	Atenolol, metoprolol, propranolol, acebutolol, bisoprolol, sotalol
III	Prolonged repolarization	Amiodarone, dronedarone, bretylium, dofetilide, ibutilide, sotalol, *N*-acetylprocainamide
IV	Calcium channel inhibition	Diltiazem, nifedipine, verapamil, bepridil

APD, action potential duration; ERP, effective refractory period.

Class I antidysrhythmics decrease the influx of sodium through fast channels in myocardial cell membranes during depolarization (phase zero of the action potential), thereby slowing the rate of rise of the action potential (V_{max}) in myocardial cells. This action results in decreased conduction velocity and increased QRS duration. Class I drugs are further divided into A, B, and C subclasses based on their respective rates of dissociation from fast sodium channels. Class IC agents dissociate slowly and therefore produce the greatest degree of QRS prolongation, even at therapeutic doses. Class IB drugs, including lidocaine, quickly dissociate from binding sites and produce no QRS prolongation at therapeutic concentrations. Class IA drugs have intermediate dissociation constants and cause mild QRS prolongation with therapeutic dosing.

Class IA drugs also have variable α-adrenergic–blocking effects, and disopyramide has relatively potent negative inotropic and anticholinergic effects. Propafenone has relatively weak β-adrenergic activity, which may be clinically important in patients on

high doses or in the approximately 7% of patients who poorly metabolize propafenone to an active metabolite, which has class IC–like properties.

Amiodarone, dronedarone, sotalol, dofetilide, and ibutilide are examples of class III drugs, which prolong repolarization and the refractory period in all cardiac tissue by blocking outward potassium channels. Because amiodarone has vasodilating and weak β-adrenergic–blocking properties, intravenous (IV) administration results in pharmacologic effects consistent with all four Vaughan–Williams classes. Dronedarone is a synthetic analog of amiodarone, available for oral use primarily in the treatment of atrial fibrillation, that lacks the thyroid and pulmonary toxicities of amiodarone (1). Like amiodarone, dronedarone exhibits electrophysiologic properties of all four Vaughan–Williams classes. Sotalol is a nonselective β-adrenergic blocker that also prolongs the refractory period throughout the conduction system, including bypass tracts. Dofetilide prolongs the action potential duration and effective refractory period without affecting conduction velocity. Dofetilide is available only to hospitals and physicians who have received appropriate dosing and treatment education, as the risk of inducing dysrhythmias is significant. Dofetilide toxicity can be minimized by paying careful attention to pretreatment QT intervals and renal function. Ibutilide is structurally related to sotalol but does not affect β-adrenergic receptors. Ibutilide activates slow sodium channels at low doses, in addition to blocking delayed rectifier potassium channels in higher doses. Class IA drugs are used to treat a wide variety of dysrhythmias of both ventricular and supraventricular origin, including re-entry tachycardias and Wolff–Parkinson–White syndrome. The efficacy of these drugs in preventing re-entry dysrhythmias is probably the result of a change from unidirectional to bidirectional block resulting from slowed conduction. Class IC drugs have very narrow therapeutic windows and are primarily used for maintenance of sinus rhythm in patients with atrial fibrillation. The Cardiac Arrhythmia Suppression Trial demonstrated increased mortality in patients given encainide or flecainide after myocardial infarction, and these IC drugs are

typically reserved for treatment of refractory supraventricular tachycardias. The class III drugs have become more prominent as initial therapy for both ventricular and supraventricular rhythm disturbances.

Compared with other cardiovascular (CV) drugs (e.g., β-blockers or calcium channel blockers), overdose with antidysrhythmic drugs is rare. Most overdoses occur in adults and are accidental. Adverse effects are common, however, occurring in 20% to 50% of patients on chronic therapy.

These drugs are well absorbed orally, and peak plasma levels following ingestion of immediate-release dosage forms usually occur within 1 to 3 hours, except with amiodarone (typically 4 to 6 hours, but up to 12 hours) and disopyramide (as a result of its anticholinergic effects). Metabolites of quinidine, encainide, propafenone, amiodarone, and dronedarone are not monitored clinically but have varying degrees of pharmacologic activity and probably contribute to overall effects. The principal metabolite of procainamide, *N*-acetylprocainamide (NAPA), prolongs repolarization (resembling Class III drugs) but is not approved for use in the United States. Amiodarone is unique in that it has a very prolonged elimination half-life (50 days); serum levels may continue to rise for a month after starting therapy.

The toxic effects of antidysrhythmics result from exaggerated therapeutic activity. Dose-dependent delays in conduction lead to variable degrees of atrioventricular block and, eventually, asystole. High drug levels also result in myocardial depression (classes IA, IC, and III) and peripheral vasodilatation (classes IA and III), which can result in profound hypotension. Central nervous system (CNS) effects appear to be independent of cardiac effects unless shock is present.

There is insufficient data to determine the minimum toxic doses for most antidysrhythmic drugs. For class IA drugs, toxicity may be expected after acute ingestions of 1 g or more. Ingestions >2.5 to 3.0 g may result in serious toxicity but survival has occurred with acute doses of up to 20 g and peak serum levels of 21.4 μg/mL (quinidine) and 77 μg/mL (procainamide). However, 2 g of

disopyramide resulted in cardiopulmonary arrest in a 16-year-old girl, and fatalities have been reported following estimated doses as low as 3.6 to 6.8 g in adults and 600 mg in a child, and serum levels of 8.3 μg/mL.

Class IC drugs appear to be more toxic than class IA drugs. Severe toxicity has occurred in a 6-month-old child who ingested a single 25-mg encainide tablet. Seizures, hypotension, bradycardia, and coma have occurred following ingestion of 3.0 to 3.5 g of encainide. Ingestion of 1.8 g of flecainide was fatal in an 18 year old, and 1.5 g has produced seizures and polymorphous ventricular tachycardia (VT). An acute overdose of 1.8 g (133 mg/kg) of propafenone in a 2-year-old child resulted in hypotension, seizures, and a prolonged QT interval. Ingestion of 8.1 g of propafenone caused seizures, coma, hypotension, and prolonged QRS interval in an adult with a propafenone serum level of 3.2 μg/mL. An overall mortality of 22.5% was reported in a retrospective review of patients with propafenone, flecainide, ajmaline, and prajmaline toxicity (2). About half of these patients became nauseated within 30 minutes of ingestion, and severe cardiac toxicity (atrioventricular block, bradycardia, pulseless electrical activity, asystole) occurred within 30 to 120 minutes after ingestion.

There is much less information about the acute toxicity of class III drugs. Amiodarone doses of 2.6 to 8.0 g have produced mild bradycardia, prolonged QT interval, and a brief episode of nonsustained VT, all with a delayed onset of 12 to 48 hours. There is limited data on dronedarone overdose, but bradycardia, QT prolongation, and heart failure can occur, even with therapeutic dosing. Sotalol toxicity may result in QT prolongation and cardiac dysrhythmias.

Excessive dosing or impaired excretion of these compounds frequently leads to toxic levels during chronic therapy. Clinical toxicity at a relatively lower serum concentration may be expected during chronic therapy as a result of prior saturation of tissue stores and the likelihood of pre-existing cardiac disease.

Local anesthetics decrease neuronal permeability to sodium ions (a similar mechanism to the cardiac antidysrhythmics), which

prevents transmembrane depolarization and subsequent propagation of the action potential. Lidocaine is a group II (amide-type) local anesthetic, and the most commonly used local anesthetic. Other group II anesthetics include bupivacaine, ropivacaine, mepivacaine, prilocaine, dibucaine, and etidocaine. A common mnemonic device notes that the local anesthetics with two letter "*i*"s in the generic name are all in the amide class.

Group I local anesthetics contain esters rather than amides and include cocaine, tetracaine, procaine (Novocaine), proparacaine, and benzocaine. Patients with a reported allergy to a local anesthetic are typically allergic to all agents of the same group (amide or ester) but may be safely given an anesthetic from the other group.

Lidocaine is well absorbed through mucous membranes and sufficient gastrointestinal (GI) tract absorption may result in toxic serum levels. Peak plasma concentrations are reached within 2 minutes of IV administration, within 10 minutes of endotracheal administration, and within 30 to 60 minutes of ingestion. Following IV injection, lidocaine is rapidly distributed to well-perfused tissues (brain and heart), with subsequent slower distribution to less well-perfused tissues such as skeletal muscle and fat. The initial distribution serum half-life is approximately 10 minutes. The peak serum concentration, which depends on the rate of administration, then rapidly declines. Because of this biphasic pattern of distribution, an infusion is required to maintain therapeutic serum concentrations following IV bolus for an antidysrhythmic effect. A standard IV dosing regimen is 1.0 to 1.4 mg/kg, followed in 10 minutes by an additional bolus of 0.7 mg/kg and a maintenance infusion of 1 to 4 mg/min (20 to 50 μg/kg/min for children).

Lidocaine and other amide class anesthetics undergo extensive liver metabolism, primarily via glucuronidation, though metabolites do not contribute significantly to clinical or toxic effects. The plasma elimination half-life of lidocaine ranges from 1.5 to 2.0 hours, and the elimination half-lives of metabolites are 3 and 5 hours, respectively. Only 5% to 10% of the parent drug is excreted unchanged into the urine. High concentrations of lidocaine

metabolites may produce toxic effects even when serum lidocaine concentrations are low. The risk of lidocaine toxicity is increased in patients with hepatic dysfunction, congestive heart failure, and shock as a result of alterations of metabolism, hepatic blood flow, and volume of distribution. Because of changes in the volume of distribution, lidocaine serum levels may be 30% higher in patients with congestive heart failure.

CLINICAL PRESENTATION

The onset of symptoms following acute oral antidysrhythmic overdose usually occurs within 4 hours and often occurs within 1 to 2 hours. However, drug absorption may continue for many hours following the ingestion of massive amounts, sustained-release preparations, or agents with anticholinergic effects. Delayed onset of toxicity is characteristic of amiodarone overdose.

Extracardiac manifestations of acute toxicity include dizziness, visual disturbances, psychosis, anticholinergic symptoms (disopyramide), hypoglycemia (disopyramide), hyperglycemia (encainide), hypokalemia, and hypersensitivity reactions (e.g., fever, rash, urticaria). Thrombocytopenia and a lupus-like syndrome (arthralgias, fever, myocarditis) with antinuclear antibodies have been well documented during chronic quinidine and procainamide therapy. Chronic amiodarone use is associated with numerous adverse effects, including corneal microdeposits, photosensitivity, hepatic dysfunction, myopathy, pulmonary fibrosis, hypo- or hyperthyroidism, and peripheral neuropathies. Dronedarone is considered less toxic than amiodarone, though adverse effects include nausea, vomiting, diarrhea, rash, and photosensitivity.

Hypotension, bradycardia, CNS depression, seizures, metabolic acidosis, and CV collapse can occur in severe poisoning. Seizures appear to be more prevalent with class IC drugs. Clinical effects associated with quinidine include seizures, immune-mediated hemolytic anemia, syncope, and cinchonism. Syncope is caused primarily by torsade de pointes but may also be associated with adrenergic blockade (orthostasis) or, rarely, idiosyncratic reactions.

Cinchonism (see Chapter 315) is associated with chronic therapy and does not appear to be dose-related. Procainamide and quinidine predictably produce hypotension if given too rapidly by IV infusion. Death can result from refractory dysrhythmias or CV collapse.

Disturbances in cardiac conduction and rhythm are the electrocardiographic (ECG) hallmarks of antidysrhythmic-agent poisoning. Excessive prolongation of the QT interval is almost always present in severe poisoning. With class IA and IC agents, this is from prolongation of the QRS interval, whereas with class III agents, it is caused by QT prolongation. In general, an increase of the QRS or QT interval by 25% is considered therapeutic, and widening by 50% or more suggests toxicity. The PR interval may also be prolonged, if there is sinus activity. Conduction disturbances and myocardial depression contribute to a host of supraventricular and ventricular dysrhythmias, including sinus bradycardia, atrioventricular dissociation, VT or fibrillation, slow idioventricular rhythm, and asystole. Torsades de pointes is a triggered (early after depolarization) polymorphous VT resulting from excessive QT prolongation, most commonly associated with class IA and class III drugs (e.g., quinidine, amiodarone, dofetilide, ibutilide).

All antidysrhythmic drugs can aggravate existing dysrhythmias or induce new ones in patients being treated for supraventricular or ventricular dysrhythmias (i.e., antidysrhythmics may be proarrhythmic) (3). The incidence of proarrhythmia is estimated at 5% to 20% and most often occurs with initiation of therapy or a dosage increase (4). Dysrhythmias should always be suspected in patients on antidysrhythmic drugs who present with syncope.

The correlation of serum levels with clinical effects depends on previous exposure to the drug, the presence of heart disease, and the degree of absorption, metabolite formation, and elimination. In general, serum levels exceeding 7, 8, and 15 μg/mL for quinidine, disopyramide, and procainamide, respectively, should be considered toxic. Lower levels may result in toxicity in patients who ingest other CV agents. Patients on chronic therapy who take an acute overdose appear to be at greater risk for severe intoxication.

Lidocaine toxicity involves the CNS and the CV system and can result from all routes of administration, but most frequently occurs during IV infusion. CNS effects have been reported in up to 47% of patients receiving IV lidocaine. Initial symptoms, such as lightheadedness, dizziness, drowsiness, and euphoria, may occur at therapeutic concentrations. At higher concentrations, more serious symptoms include confusion, hearing loss, dysarthria, visual disturbances, ataxia, agitation, and muscle twitching, which may lead to seizures and coma. Seizures may be prolonged. CV toxicity is rare and usually occurs from rapidly administered IV infusions. When serum concentrations are >11 μg/mL, the refractory period is decreased, automaticity and myocardial contractility are depressed, and hypotension and bradycardia ensue. Conduction abnormalities include sinus bradycardia, atrioventricular block, complete heart block, and sinus arrest. Conduction defects are more common in patients with preexisting bundle-branch abnormalities.

Mucosal lidocaine absorption bypasses hepatic first-pass metabolism, making lidocaine more bioavailable than by intestinal absorption. Seizures have occurred in children following mucosal application of 2% to 4% viscous lidocaine. Therefore, topical or oral lidocaine for the treatment of painful oral lesions in children should be used cautiously, if at all.

Seizures have also occurred following lidocaine infiltration. During laceration repair, the total dose for infiltration of lidocaine without epinephrine should not exceed 4.5 mg/kg, or 7.0 mg/kg of lidocaine with epinephrine. The standard 1% lidocaine solutions contain 10 mg/mL of lidocaine; thus, the maximal volumes used for local infiltration in a 70-kg adult patient are roughly 30 mL without epinephrine and 50 mL with epinephrine. Fortunately, most wounds repaired in the emergency department (ED) only require small volumes of anesthetic.

The neurologic and cardiac toxicities of other local anesthetics are similar to that of lidocaine. For example, patients referred to the ED from dental offices often have CNS toxic effects as a result of injection of procaine or other local anesthetics for dental procedures. Several local anesthetics, particularly benzocaine, have

also been reported to cause methemoglobinemia (see Chapter 335). Benzocaine is found in over-the-counter infant teething gels and adult oral anesthetics and is also used as a topical anesthetic to aid in endotracheal or gastric intubation and various endoscopic procedures.

DIFFERENTIAL DIAGNOSIS

Similar bradyarrhythmias may be caused by β-blockers, calcium antagonists, cholinergic agents (carbamate and organophosphate insecticides), digitalis, clonidine, lithium, and cyclic antidepressants. QRS and QT interval prolongation may result from poisoning with antihistamines, phenothiazines, cyclic antidepressants, lithium, hypermagnesemia, and hyperkalemia. Ventricular tachyarrhythmias may occur with sympathomimetics.

Stimulants, hypoglycemia, hypoxia, and metabolic disturbances should be considered in the differential diagnosis of patients with CNS manifestations. Patients presenting with apprehension, anxiety, or other neurologic symptoms after very recent dental work, medical procedures on the upper aerodigestive tract, or wound repair would strongly suggest the possibility of local anesthetic toxicity. Methemoglobinemia should be considered in a patient who becomes cyanotic and is responding poorly to oxygen therapy after exposure to local anesthetics.

ED EVALUATION

The history should include the exact product, strength (immediate or sustained release), the amount ingested, the time ingested, and treatment before arrival. Any history of CV disease should be elucidated. Mechanisms for chronic toxicity, such as excessive dosing, exacerbation of congestive heart failure, or change in renal function, should be investigated.

The physical examination should focus on vital signs, with attention to CV stability and respiratory and neurologic status. An ECG should be obtained as soon as possible to check for conduction delays and dysrhythmias. In most patients with local anesthetic

toxicity, an extensive metabolic workup will not be necessary. Patients suspected of having toxicity from antidysrhythmic drugs are often taking these agents therapeutically and often have significant underlying disease. For them, laboratory evaluation should include a blood-glucose level; electrolyte analysis; blood urea nitrogen, creatinine, and magnesium measurement; liver-function tests; and appropriate serum drug levels, if available. Chest radiography and blood-gas analysis are added for patients with depressed levels of consciousness or serious dysrhythmias. If suspected, venous or arterial blood should be sent for a methemoglobin level.

KEY TESTING

- ECG for all patients with antidysrhythmic poisoning
- Poisoned patients need serum electrolytes measured, renal- and hepatic-function tests
- Serum drug levels (if available) can be helpful

ED MANAGEMENT

Advanced life-support measures should be instituted as necessary. All patients suspected of antidysrhythmic drug toxicity should have IV access, continuous cardiac monitoring, and pulse oximetry. Unstable patients need close hemodynamic monitoring, supplemental oxygen, and airway management as indicated clinically. Acid–base, electrolyte, and magnesium derangements should be corrected. Potassium should be replaced cautiously, because hypokalemia may protect against cardiotoxicity from quinidine (and possibly other agents). Seizures are treated with standard doses of IV benzodiazepines and barbiturates.

Hypotension is initially treated cautiously with IV normal saline. Infusions of sodium bicarbonate can reverse hypotension associated with class IA and IC drugs. Hypotension refractory to volume expansion may require the use of direct-acting vasopressors or inotropes (epinephrine, norepinephrine, dopamine), aortic balloon counterpulsation, or cardiopulmonary-bypass (CPB) pump support.

Sodium bicarbonate (2 mEq/kg IV bolus) should be given to patients with hypotension, prolonged QRS intervals, premature ventricular contractions (PVCs), and monomorphic VT if class I antiarrhythmic toxicity is suspected. Sodium bicarbonate has beneficial effects by increasing the serum sodium level to help offset the sodium channel blockade, by increasing serum-protein binding (e.g., decreasing free drug) in a more alkalotic serum, and by driving drugs off the sodium channels. Symptomatic bradycardia or atrioventricular dissociation will probably require ventricular pacing if there is inadequate response to atropine and sodium bicarbonate. Successful pacemaker capture may require concomitant epinephrine therapy.

After sodium bicarbonate, lidocaine is the drug of choice for ventricular ectopy (except, of course, for patients with lidocaine toxicity). Other antidysrhythmic drugs in the same class are contraindicated for treatment of dysrhythmias. Torsade de pointes usually responds to isoproterenol infusion (1 to 6 μg/min) and atrial or ventricular overdrive pacing; a heart rate of 150 beats/min is usually required. IV magnesium sulfate (1 to 4 g in several minutes to 1 hour, depending on the hemodynamic stability) may also be effective.

Recent animal studies and human case reports suggest that intravenous lipid emulsion (ILE) may be effective and potentially life-saving in patients with refractory cardiotoxicity associated with local anesthetics (5). Most evidence exists for bupivacaine toxicity, though there are case reports of success following overdose of other local anesthetics including lidocaine. Although the optimal dose remains undefined, a 1.5-mL/kg bolus infusion of 20% lipid emulsion followed by 0.25 mL/kg/min for 30 to 60 minutes is generally recommended. An additional bolus can be considered for continued asystole, though total doses exceeding 10 mL/kg are not recommended. The mechanism of action of ILE is unclear but possibilities include (1) providing an intravascular “lipid sink” to pull drug from receptors, (2) providing an energy source for cardiac myocytes, or (3) activation of calcium and potassium channels by fatty acids (6). Patients in cardiac arrest have been successfully

resuscitated following treatment with ILE. Patients with anesthetic-induced symptomatic methemoglobinemia can be treated with methylene blue (as described in Chapter 335).

Once the patient has been stabilized, activated charcoal should be given to decontaminate the GI tract in awake patients with recent ingestions. Patients whose vital signs can be supported during endogenous drug elimination usually recover fully. Efforts to enhance elimination of these compounds have had variable success. Patients should be adequately hydrated to maintain renal perfusion. In the presence of renal failure, hemodialysis can increase the clearance of NAPA fourfold and that of procainamide twofold.

CRITICAL INTERVENTIONS

- Establish IV access, initiate cardiac monitoring:
- 12-lead ECG in patients with potential toxicity from antidysrhythmic agents or local anesthetics.
- Administer sodium bicarbonate to patients with hypotension, prolonged QRS interval, PVCs, and monomorphic VT as a result of class I antiarrhythmic poisoning.
- Administer magnesium sulfate IV, and induce sinus tachycardia with isoproterenol or overdrive pacing in patients with torsade de pointes.
- Consider intravenous lipid therapy for CV collapse due to local anesthetic toxicity.

DISPOSITION

Patients with local anesthetic exposures can be discharged once free of neurologic and cardiac toxic effects, often within just a few hours. Those with persistent CNS symptoms or an abnormal ECG should be admitted to a monitored setting.

Patients who remain asymptomatic and have a normal ECG, 6 hours following antidysrhythmic agent ingestions can usually be safely discharged. A 12-hour observation period is recommended if a sustained-release preparation is involved. Patients with amiodarone overdose should be admitted for prolonged observation.

Patients who are symptomatic or exhibit ECG evidence of cardiotoxicity from either acute or chronic intoxication need admission to a monitored bed. Those patients with CV instability should be admitted to an intensive care unit. Patients with severe toxicity should be admitted to a facility with cardiopulmonary bypass and aortic balloon counterpulsation capabilities. Patients with an intentional overdose should undergo psychiatric evaluation before discharge.

Common Pitfalls

- Failure to appreciate that severe toxicity can result from therapeutic doses of antidysrhythmic agents.
- Failure to consider the possibility of drug-induced dysrhythmias as a cause of syncope and weakness in patients taking antidysrhythmic agents.
- Failure to appreciate that drug-induced dysrhythmias may resemble the ones for which the drug was prescribed; thus, drug levels should be checked before further drug treatment.
- Failure to check the dose and concentration of local anesthetic solutions and to adhere to recommended dosing guidelines.
- Failure to use cardiac monitoring on patients receiving IV regional local anesthetics and large doses of local anesthetics by infiltration.
- Failure to appreciate that local anesthetics can cause both CNS excitation and depression.
- Failure to warn patients and parents of children that multiple doses of oral viscous lidocaine can be toxic and that the preparation should not be swallowed.

CHAPTER 322

Centrally Acting Antihypertensive Agents

Susan E. Farrell

The centrally acting antihypertensive agents include the first-generation agents: clonidine, guanabenz, guanfacine, methyldopa, and reserpine; and the second-generation agents: moxonidine and rilmenidine. All of these agents reduce blood pressure through their central inhibition of sympathetic tone mediated by their agonist activity at α_2-adrenergic and I_1-imidazoline receptors in the nucleus tractus solitarii of the rostral ventrolateral medulla. The ultimate effect of their actions at these central vasomotor centers is a reduction of catecholamine concentrations and diminished autonomic sympathetic outflow from the central nervous system (1–3).

The first-generation agents are associated with a greater number of adverse effects due to their activity at both the α_2-adrenergic and the I_1-imidazoline receptors. In contrast, moxonidine and rilmenidine are selective for the I_1-imidazoline receptor, which limits their adverse effects. These findings suggest that the centrally mediated antihypertensive effects of these drugs are likely at the I_1-imidazoline receptor, in cooperation with some activity at the α_2-adrenergic.

Clonidine, the prototypical first-generation centrally acting antihypertensive agent, is an imidazoline derivative first synthesized in 1962 as a topical nasal decongestant. Clonidine is available in oral formulations, combination preparations, a transdermal patch,

and as intravenous solution. It is a component of multidrug antihypertensive therapy in patients with comorbidities such as diabetes mellitus or acute renal failure, in patients with sympathetically driven forms of hypertension, and for the treatment of perioperative hypertension. Clonidine has also been used as adjunctive therapy for heart failure and chronic pain syndromes, in migraine prophylaxis, in treatment of posttraumatic stress disorders, and for menopausal flushing (2). Clonidine is used to ameliorate the symptoms of alcohol, narcotic, nicotine, and γ-hydroxybutyrate (GHB) withdrawal and has increasingly become second-line therapy for attention-deficit hyperactivity disorders and Tourette syndrome (4).

Reports of fatal toxicity as a result of clonidine overdose are rare. A 7-year retrospective study of >10,000 pediatric clonidine poisoning exposures found major effects in only 2% of the children, including 23 cases of respiratory arrest and 1 fatality (4). However, the incidence of clonidine exposure and potential toxicity is increasing in children, associated with a greater prevalence of its use for pediatric behavioral problems (4–6).

Moxonidine and rilmenidine are structural analogs of clonidine, but more selective in their effect; available in other countries but not yet in the United States. In addition to their antihypertensive effects, these agents may also be beneficial in the management of metabolic syndrome (7). Both agents have long durations of action (up to 24 hours), and dose adjustment is necessary in renal insufficiency. These drugs are contraindicated in patients who are taking monoamine oxidase inhibitors (2). Moxonidine is contraindicated in the setting of sick-sinus syndrome, bradydysrhythmias, and renal failure; and rilmenidine is contraindicated in severe depression and renal failure. There are no reports of overdose of these agents.

CLINICAL PRESENTATION

Signs and symptoms of toxicity of the centrally acting antihypertensive agents are similar, usually occur within 30 to 60

minutes after ingestion, and consist of bradycardia, respiratory depression, lethargy, coma, and miosis. Hypotension, hypothermia, and hyporeflexia are common signs of serious toxicity and may sometimes be delayed by several hours.

In adults, significant clinical toxicity can occur after the ingestion of 1 to 2 mg of clonidine. Children may develop serious toxicity after the ingestion of a single adult therapeutic dose of clonidine (0.1 to 0.3 mg) (8). Toxicity does not always correlate well with the amount ingested, and a specific lethal dose has not been determined.

Intermittent apnea, responsive to physical or auditory stimuli, has been noted in children, and respiratory failure requiring mechanical ventilation has been reported. Clonidine interacts with other CNS depressants, and the concomitant ingestion of these substances can aggravate CNS depression and contribute to coma.

Hypertension and hypertensive crisis have been reported in the initial phase of clonidine or methyldopa overdose. This elevation of blood pressure resolves spontaneously and is quickly and precipitously followed by hypotension.

Adverse effects of maintenance therapy with clonidine, and most of the first-generation centrally acting antihypertensives, is due to their agonist activity at central α_2-adrenergic receptors, and include sedation and dry mouth, orthostatic hypotension, fatigue, constipation, sexual dysfunction, and dizziness. These adverse effects can be prominent in elderly patients. A positive direct Coombs test develops in 10% to 20% of patients taking methyldopa, but hemolysis is seldom a clinical problem. Hypersensitivity hepatitis occurs in 6% of patients using methyldopa (2). Alternative antihypertensive agents may be safer options in patients with sinus node or atrioventricular conduction abnormalities. Skin reactions including erythema, vesiculation, and induration have been associated with transdermal patch application.

The clonidine withdrawal syndrome is characterized by symptoms consistent with excessive sympathetic autonomic activity including rebound hypertension, tachycardia, tremulousness, insomnia,

anxiety, sweating, and palpitations (2,9). Withdrawal can occur after the abrupt cessation of chronic clonidine therapy, especially after doses of >1.0 mg/d (2). A case report of abrupt clonidine withdrawal in an elderly female was associated with accelerated hypertension, tachycardia, and myocardial infarction within 24 hours (9).

The incidence of adverse effects due to moxonidine and rilmenidine is less, presumably because of their greater selectivity for I_1-imidazoline receptors compared with α_2-adrenergic receptors (7).

DIFFERENTIAL DIAGNOSIS

The presenting symptoms of poisoning with the centrally acting antihypertensive agents may be clinically indistinguishable from toxicity caused by other α_2-adrenergic and imidazoline-receptor agonists such as brimonidine, naphazoline, oxymetazoline, tetrahydrozoline, and xylometazoline, common components of topical ophthalmic or nasal-decongestant preparations.

Because of the constellation of miosis, altered mental status, and respiratory depression, toxicity is often confused with that of opioid overdose. Centrally acting antihypertensive-agent toxicity may also resemble that caused by overdose of sedative–hypnotics, β-adrenergic antagonists, calcium channel blockers, and digitalis. Hypoglycemia, sepsis, hypothermia, cerebrovascular accident, and head trauma should also be considered in the differential diagnosis.

ED EVALUATION

The evaluation of patients with known or suspected centrally acting antihypertensive-agent overdose includes continuous assessment of airway maintenance, ventilation, and cardiovascular status, including continuous electrocardiographic monitoring for bradycardia, and an evaluation to rule out concomitant trauma or nondrug-related medical abnormalities.

The diagnosis of poisoning is based on the history and clinical findings. There are no specific laboratory or clinical tests of

diagnostic value. These agents are not detected on routine drugs of abuse screens. Quantitative drug levels are unavailable in the acute clinical setting and are of no value in management. Radiographic imaging, routine laboratory tests, and toxicologic analysis are useful only to rule out or confirm concomitant pathology.

KEY TESTING

- Electrocardiogram: to evaluate bradycardia and conduction abnormalities
- Fingerstick or bedside glucose testing: to evaluate for hypoglycemia

ED MANAGEMENT

Prehospital care is supportive and consists of continuous electrocardiographic monitoring and maintenance of intravenous access. The routine administration of naloxone and evaluation or treatment for hypoglycemia are appropriate in symptomatic patients. Activated charcoal is the preferred method of gastrointestinal decontamination with early and large ingestions. In the case of clonidine transdermal patch ingestion, there may be a role for whole-bowel irrigation.

Treatment of centrally acting antihypertensive-agent overdose is primarily supportive and symptomatic. Respiratory depression and periodic apnea may require tracheal intubation and assisted ventilation. Bradycardia usually reverses with intravenous atropine, repeated if necessary, based on heart rate and blood pressure response. Hypotension usually responds to crystalloid infusion. Occasionally, vasopressors may be required and dopamine, epinephrine, and cardiac pacing are of theoretical benefit, but their use in clonidine poisoning has not been described. In the unusual case in which early, transient hypertension occurs, aggressive antihypertensive treatment should be avoided because of the potential for subsequent serious and prolonged hypotension (10). Elevated blood pressure usually requires only observation, although occasionally a short-acting titratable antihypertensive such as

nitroprusside may be warranted. Hypothermia and coma are treated with supportive care. Clinical recovery is usually noted within 24 to 48 hours. Hemodialysis, charcoal hemoperfusion, and forced diuresis are of no proven value. Because clonidine is excreted unchanged in the urine, adequate urine output should be assured.

There are no proven antidotes for centrally acting antihypertensive-agent overdose. Naloxone has been used to reverse lethargy and respiratory depression associated with these agents, but the response is inconsistent. Naloxone's use is acceptable as a therapeutic trial in patients with depressed mental status. The optimal dose of naloxone in this setting is unknown, but doses similar to those used for opioid poisoning have been suggested. Patients who are administered naloxone should be closely observed for hemodynamic deterioration and recurrent respiratory depression.

The acute symptoms of clonidine withdrawal have been treated with labetolol for control of elevated blood pressure and diazepam for tremor and agitation (9). The clonidine withdrawal syndrome is best treated by the reinstitution of clonidine therapy and tapering of the dose over 5 to 10 days. This approach can be used in the treatment of withdrawal from other similar agents.

CRITICAL INTERVENTIONS

- Establish intravenous access, and institute continuous respiratory and cardiac monitoring in patients with acute overdose or acute withdrawal.
- Keep advanced life-support airway equipment and cardiovascular drugs readily available.

DISPOSITION

Patients who remain asymptomatic 6 hours after ingestion and who have normal vital signs may be discharged from the emergency department with appropriate psychiatric or social service follow-up. Symptomatic patients require admission to a medical unit capable of continuous cardiac and respiratory monitoring. There is no known

cyclical nature to clonidine overdose, and improvement is not followed by relapse. Patients may be safely transferred to another facility with advanced life-support measures during transport.

Common Pitfalls

- Failure to appreciate that clonidine poisoning may result in severe CNS, respiratory, and cardiovascular depression.
- Misdiagnosis of clonidine poisoning as narcotic overdose because of the constellation of miosis, altered mental status, and respiratory depression.
- Overly aggressive treatment of early, transient hypertension, especially with long-acting agents.
- Reliance on unproved antidotes rather than supportive care in the treatment of toxicity.
- Failure to consider the possibility of child abuse or attempted homicide in children with overdose and to address psychiatric issues in patients with suicide attempts.

CHAPTER 323 Beta Blockers

Fermin Barrueto, Jr.

β-Blockers competitively block β-adrenergic receptors, part of the sympathetic nervous system with three main subtypes (β_1, β_2, and β_3) that regulate physiology in various locations in the body (Table 323.1). Their blockade decreases the intracellular concentration of cyclic adenosine monophosphate (cAMP), a secondary messenger that mediates the cellular effects of β-stimulation.

TABLE 323.1

	Anatomic Location	Effect of Receptor Agonism
β_1	Heart	Increase inotropy and chronotropy
	Eye	Increase aqueous humor production
	Kidney	Increase renin secretion
β_2	Smooth muscle	Relaxation around bronchi and vasculature
	Skeletal muscle	Glycogenolysis, K^+ uptake
	Liver	Glycogenolysis and gluconeogenesis
β_3	Adipose	Lipolysis

The clinical effects of β-blockers vary with regard to β-receptor selectivity, α-receptor blocking activity, lipophilicity, intrinsic sympathomimetic (β-receptor agonist) activity, and membrane-stabilizing activity (MSA) (Table 323.2). β_1-Selectivity is preferred for cardiovascular therapy to avoid the detrimental effects of β_2-blockade, such as bronchoconstriction. Labetalol and carvedilol are β-blockers that also antagonize α-adrenergic receptors, although not as prominently as β-receptors. These medications may exacerbate

hypotension as a result of vasodilation. β-Blockers with MSA inhibit fast sodium channels, which can lead to QRS prolongation and ventricular dysrhythmias. In overdose, selective activity is often lost, and most β-blockers have similar toxicologic effects.

TABLE 323.2

	Receptor Selectivity	Lipophilicity	Intrinsic Sympathomimetic Activity	Membrane-Stabilizing Activity
Acebutolol	β_1	Low	+	++
Atenolol	β_1	Low	–	–
Betaxolol	β_1	Low	–	++
Bisoprolol	β_1	Low	–	–
Carteolol	β_1,β_2	Low	+	–
Carvedilol	α_1,β_1,β_2	High	–	–
Esmolol	β_1	Low	–	–
Labetalol	α_1,β_1,β_2	Mod	–	+
Metoprolol	β_1	Mod	–	+
Nadolol	β_1,β_2	Low	–	–
Nebivolol	β_1	Low	–	–
Oxprenolol	β_1,β_2	High	+	++
Pindolol	β_1,β_2	Mod	+	+
Propranolol	β_1,β_2	High	–	++
Sotalol	β_1,β_2	Low	–	–
Timolol	β_1,β_2	Mod	–	–

β-Blockers also vary with respect to protein binding, volume of distribution, route of elimination, and half-life (Table 323.3). They are generally well absorbed after ingestion, with peak levels and effects occurring 1 to 2 hours after a therapeutic dose. Because their duration of action is relatively short (6 hours or less), extended-release formulations were developed, to allow for less frequent dosing.

TABLE 323.3
Pharmacokinetics of α-Blockers

Agent	Dose (mg)[a]	Absorption (%)	First-Pass Metabolism	Protein Binding (%)	Distribution (L/kg)	Volume of Elimination	Route of Half-Life (hrs)
Acebutolol	200–400	70	Yes	25	2.3	Renal	6
Atenolol	50–100	50	No	15	0.7	Renal	6–9
Betaxolol	10–40	100	Yes	50	6.1	Hepatic	14–22
Bisoprolol	5–40	90	No	30–36	2.7–3.1	Hepatic	11
Carvedilol	2.5–10	>90	Yes	98	1.6	Hepatic	7–10

Timolol	20–60	>90	No	10	1.5	Renal	4–5

[a]Single oral adult dose.

CLINICAL PRESENTATION

Most accidental β-blocker overdoses are relatively minor and do not result in significant toxicity, particularly in children (1,2). Large doses or the combination of a β-blocker with a calcium channel blocker can result in significant morbidity and mortality (2).

Bradycardia and hypotension are the most common effects after overdose (1). Nausea and vomiting can occur. Hypoperfusion can lead to lethargy, decreased mental status, stroke, myocardial infarction, mesenteric ischemia, renal insufficiency, with pale and clammy skin.

Highly lipophilic agents and those with MSA can affect the CNS directly to cause altered mental status despite a normal blood pressure. Delirium, coma, and seizures may occur in severe poisoning.

If the SA node is affected, sinus bradycardia may progress to sinus pauses or arrest. Negative inotropic effects add to cardiotoxicity, particularly with β-blockers that have MSA (3). β-Blockers that have MSA can cause delayed depolarization with QRS prolongation and ventricular tachyarrhythmias (3,4). Sotalol is unique in that it also blocks delayed rectifier potassium channels, which results in delayed repolarization with QT prolongation, and can cause torsade de pointes (polymorphic) ventricular tachycardia and other lethal ventricular dysrhythmias (5).

In overdose, all β-blockers can cause β_2-antagonism that leads to bronchospasm. This scenario may be more prominent and dangerous in patients with asthma or chronic obstructive pulmonary disease (1). Hypoglycemia and hyperkalemia are common, although they are usually mild and not clinically significant (1). Hypoglycemia may be more common in children.

DIFFERENTIAL DIAGNOSIS

Diseases that cause bradycardia include sick sinus syndrome, inferior wall myocardial infarction, hypothermia, and carotid sinus hypersensitivity. Other drugs that can cause bradycardia include calcium channel blockers, cardiac glycosides, cholinergic agents, α_2-agonists, opioids, and sedative–hypnotics.

Like β-blockers, diltiazem and verapamil have strong negative inotropic and chronotropic effects. Dihydropyridine calcium channel blockers (e.g., nifedipine, nimodipine, and amlodipine) typically cause reflex tachycardia in response to vasodilation and hypotension. Unlike β-blocker overdose, the mental status is often normal and calcium channel blockers cause hyperglycemia rather than hypoglycemia. Cardiac glycoside (e.g., digoxin) poisoning usually does not cause hypotension until a nonperfusing dysrhythmia occurs. Additionally, cardiac glycoside overdose produces characteristic ECG patterns.

Cholinergic agents (e.g., organophosphorus insecticides) cause diarrhea, lacrimation, urination, miosis, and vomiting along with bradycardia, bronchorrhea, and bronchoconstriction. Overdose with opioids, sedative hypnotics, and α_2-agonists may lead to mild bradycardia and hypotension associated with a depressed mental status, but cardiac conduction disturbances are rare.

ED EVALUATION

The history should include the time and amount of drug(s) taken, treatment in the field (if any), the time of onset and nature of symptoms, known medical or psychiatric problems, and current drug therapy. Determining whether the β-blocker is a sustained-release

preparation or if there were any co-ingestants with cardiovascular effects is particularly important.

The physical examination should focus on the vital signs, cardiopulmonary system, and neurologic status. Continuous cardiac monitoring and a 12-lead ECG may reveal AV nodal dysfunction with PR interval prolongation and AV block (4). A fingerstick or serum glucose concentration should be obtained, particularly with an abnormal mental status. Blood gases, chemistry panel to check for hypokalemia, complete blood count, acetaminophen level, toxicology testing, and chest radiograph (CXR) should be obtained when clinically indicated.

KEY TESTING

- ECG (which may be repeated) in patients with changes in heart rate, intervals, or dysrhythmia
- Glucose and potassium should be monitored in symptomatic patients
- Complete blood count, chemistries, CXR, and other laboratory testing as needed for supportive care

ED MANAGEMENT

Advanced cardiac life-support measures should be instituted as needed. Activated charcoal should be considered if ingestion occurred within 1 hour. If a sustained-release preparation has been ingested, activated charcoal can still be considered even later than an hour after ingestion.

Patients with bradycardia with normal blood pressure need only close monitoring. For bradycardic and hypotensive patients, a stepwise approach is recommended in which interventions, each employed to a maximal degree, are successively applied and the hemodynamic response assessed. In severely poisoned patients, multiple therapies must be instituted and maintained simultaneously. Hypotension can initially be treated with intravenous fluids. If bradycardia is also present, atropine, 1 mg intravenously (0.02 mg/kg; minimum dose, 0.1 mg in children), repeated in 5 minutes as

necessary, can be given but is frequently ineffective in β-blocker overdose.

Glucagon (5 mg intravenously over 5 minutes; 50 to 100 μg/kg in children) may be effective for hypotension, even in the absence of bradycardia. If there is no effect after 10 to 15 minutes, the dose should be repeated. Patients who respond should be given an infusion of glucagon at a rate of 1 to 5 mg/hr (50 μg/kg/hr in children). Glucagon bypasses the β-blockade by activating a G-protein bound to adenylate cyclase and also activating the cascade indirectly to increase intracellular cAMP (Fig. 323.1). Because glucagon often causes vomiting, prophylactic anti-emetics may be useful. Although there are no human controlled trials, animal studies show that glucagon has a positive chronotropic effect in β-blocker overdose but a minimal effect on mean arterial pressure (6).

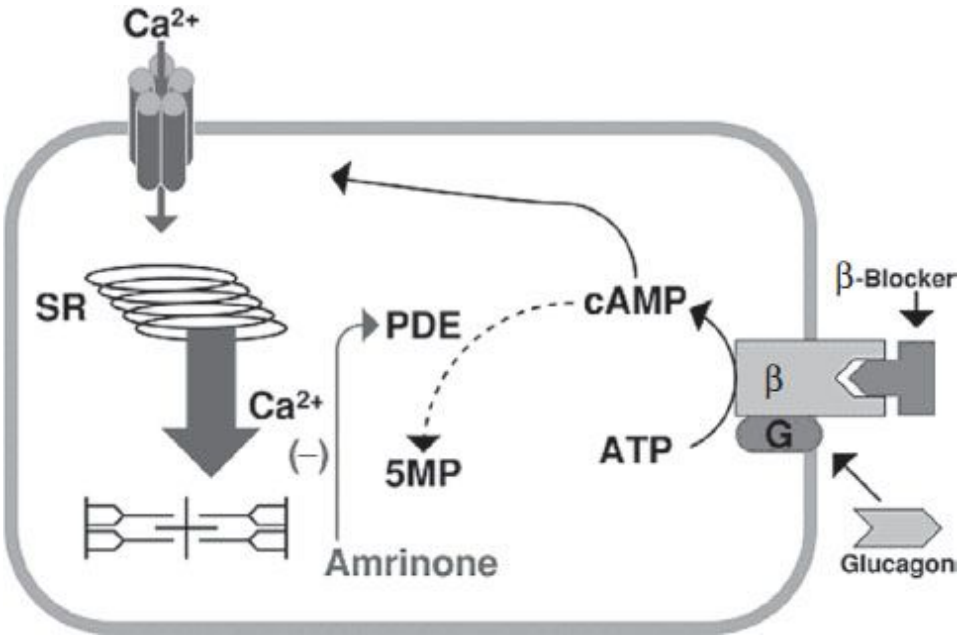

FIGURE 323.1 The effects of amrinone and glucagon on cAMP. Extracellular Ca^{2+} influx will cause the SR (sarcoplasmic reticulum) to release Ca^{2+} exponentially to bind the excitation–contraction apparatus, made of actin and myosin filaments. cAMP increases intracellular Ca^{2+} and is created by an adenylate cyclase that is part of the β-receptor and broken down by PDE (phosphodiesterase). Glucagon can activate the G protein, bypass the β-receptor if

blocked, and increase cAMP. Amrinone inhibits PDE, thus also increasing cAMP. (FIGURE by Walter Barrueto.)

Intravenous calcium assists with inotropy in animals (7) and in reversing hypotension in humans (8,9). The dose is the same as for calcium channel blocker poisoning (see Chapter 324). Vasopressors are often necessary. There is no human data to show which pressor is more efficacious than another, so dobutamine, epinephrine, and dopamine have all been used, but the required dose is often much higher than what is traditionally used (1). Invasive cardiac monitoring or echocardiography can help to identify the agent that brings the best response and to titrate to the desired effect.

If the patient requires vasopressors, hyperinsulinemia–euglycemia (insulin and glucose) therapy has been anecdotally effective (10,11). The same protocol as in calcium channel blocker poisoning (see Chapter 324) should be used. In canine propranolol poisoning, this therapy was superior to glucagon and epinephrine (12). Hyperinsulinemia–euglycemia therapy may work by maximizing myocardial glucose utilization, augmentating cytosolic calcium concentrations, or possibly through a direct inotropic effect (12). The response may be delayed 15 to 60 minutes, so other therapies must be continued.

A phosphodiesterase inhibitor such as amrinone is of theoretical benefit but has propensity to cause vasodilation, is difficult to titrate, and often does not improve the bradycardia seen in β-blocker exposure (see Fig. 323.1) (6). This treatment is controversial and not recommended. If a lipophilic β-blocker is involved or if the patient is hemodynamically unstable or critical, one can consider using 1.5 mL/kg of 20% lipid emulsion as a single bolus with an option to repeat the bolus. This has been effective with local anesthetics and overdoses involving lipophilic drugs like verapamil and propranolol (13).

Should pharmacologic therapy be ineffective, intravenous cardiac pacing can be used to treat bradycardia; however, it is likely that there will be little improvement in cardiac output, and difficulty with capture is common. Some authors have reported a decrease in blood

pressure, which may be caused by loss of atrial contraction and/or impaired ventricular relaxation. Intra-aortic balloon pump counterpulsation and partial or complete cardiac bypass pump support have been used in severe poisoning (14). Hemodialysis has been used with apparent success for atenolol and sotalol overdose; charcoal hemoperfusion might be effective for water-soluble β-blockers that have a low volume of distribution like atenolol and acebutolol (15,16). Patients who might benefit most from extracorporeal elimination measures are already hypotensive, making these procedures technically difficult and potentially hazardous. Continuous veno-venous hemodialysis is another alternative, but has never been studied.

In patients with sotalol poisoning, hypokalemia and hypomagnesemia should be corrected. The treatment of recurrent torsade de pointes includes overdrive pacing and magnesium infusion (5). Bradycardia and hypotension are treated the same as with other β-blockers.

CRITICAL INTERVENTIONS

- Treat with intravenous fluids for hypotension.
- If hypotension and bradycardia persist, use glucagon, calcium, and high-dose pressors.
- Hyperinsulinemia–euglycemia therapy should be considered if the patient remains unstable.
- Consider transvenous pacing, intra-aortic balloon pump, or extracorporeal circulatory support measures for patients who have not responded to other treatment modalities.
- Certain β-blockers (e.g., atenolol, sotalol) are amenable to hemodialysis or hemoperfusion.

DISPOSITION

Patients with β-blocker ingestions who remain or become asymptomatic 6 hours after ingestion can be discharged or medically cleared for a psychiatric disposition (2,3). If sotalol or a sustained-release preparation is ingested, a 12- to 24-hour observation period

is recommended since sotalol has produced symptoms, QT prolongation, and other dysrhythmias up to 20 hours from the time of ingestion (5). With extended-release preparations, prolonged and erratic absorption may result in delayed toxicity. Patients with abnormal vital signs, mental status, or ECG findings require continuous cardiac monitoring and frequent vital signs. This usually requires admission to an intensive care unit. The hospital's supply of glucagon should be ascertained, as many pharmacies are not prepared to administer the large doses required to treat β-blocker exposures. Transfer of the patient to a tertiary care facility should be considered in cases of severe poisoning where intra-aortic balloon pump or other advanced therapies are available. Psychiatric consultation should be obtained for patients with intentional ingestions prior to discharge. Education in poison prevention, particularly in children, should also be provided prior to discharge.

Common Pitfalls

- Failure to determine whether the drug ingested was an immediate- or extended-release formulation, potentially leading to undertreatment and inappropriate disposition.
- Failure to check a fingerstick blood glucose, as β-blockers can cause hypoglycemia.
- Failure to appreciate that β-blockers with MSA can cause delayed depolarization, cardiac conduction disturbances (QRS prolongation), and ventricular tachyarrhythmias.
- Failure to anticipate seizures with lipophilic β-blockers such as propranolol.
- Failure to appreciate that sotalol blocks potassium channels, causing a prolonged QT interval and torsade de pointes, and has late presenting symptoms.
- Failure to plan for severe poisonings that are likely to require invasive monitoring, multiple pharmacologic treatments, and mechanical hemodynamic support.

ACKNOWLEDGMENTS

The author gratefully acknowledges the contributions of Linda Kesselring and Christopher H. Linden to previous editions of this chapter.

CHAPTER 324 Calcium Channel Antagonists

Matthew D. Sztajnkrycer

Calcium is critical for cellular function, involved in diverse processes including myocyte excitation–contraction coupling, intracellular second-messenger signaling, release of neurotransmitters and hormones, and initiation and propagation of the action potential. Intracellular calcium is largely sequestered within the sarcoplasmic reticulum and released through direct receptor activation or through second-messenger–mediated systems. Calcium channels are found in the membranes of many cells, including vascular smooth muscle, the myocardium, and the specialized pacemaker and conducting fibers of the heart. Three general classes of calcium channel have been identified, based on mechanism of activation: (1) voltage-operated calcium channels (VOCCs), (2) receptor-operated calcium channels, and (3) second-messenger–operated calcium channels.

Calcium channel antagonists (CCAs) are a structurally diverse group of drugs used in the treatment of supraventricular tachyarrhythmias, hypertension, angina, heart failure, and subarachnoid hemorrhage and in the prevention of migraine headaches. Eleven CCAs are currently approved by the US Food and Drug Administration for use in the United States (Table 324.1); verapamil and amlodipine possess pediatric FDA approval. All act by depressing the activation, inactivation, and recovery of the L-type VOCC, and are thus classified as class IV antiarrhythmics. Cardiovascular (CV) responses to therapeutic doses vary considerably (see **Tables 324.1** and **324.2**).

TABLE 324.1
Therapeutic Doses of Calcium Channel Blockers

Drug	Trade Name	Usual Dose	Therapeutic Range
Verapamil	Calan, Isoptin, Verelan		
Oral		80–160 mg tid	15–100 ng/mL
Intravenous		5–10 mg	
Diltiazem	Cardizem, Dilacor	30–90 mg qid	30–130 ng/mL
Nifedipine	Adalat, Procardia	10–40 mg tid	25–100 ng/mL
Nicardipine	Cardene	20–40 mg qid	28–50 ng/mL
Nimodipine	Nimotop	60 mg q4h	7–96 ng/mL
Felodipine	Plendil	5–20 mg qd	0.7–8.0 ng/mL
Isradipine	DynaCirc	2.5–10.0 mg bid	2–8 mg/mL
Nisoldipine	Sular	20–40 mg qd	
Amlodipine	Norvasc	2.5–10.0 mg qd	5–15 mg/mL
Clevidipine	Cleviprex	Initial dose 1–2 mg/hr; maintenance 4–6 mg/hr	
Bepridil	Vascor (no longer available in US)	200–400 mg qd	

TABLE 324.2
Cardiovascular Response to Drug Therapy

	Verapamil	Diltiazem	Nifedipine and Other Dihydrophyridines	Bepridil
Heart rate (sinoatrial node)	⇑ or ⇓	⇓	⇑	⇓
Atrioventricular nodal conduction	⇓⇓	⇓	⇑	⇓
Smooth-muscle tone	⇓⇓	⇓	⇓⇓⇓	⇓
Blood pressure	⇓	⇓	⇓⇓	⇓
Contractility (in vivo)	⇓⇓	⇓	⇑ or ⇓	⇓

CCAs are well absorbed after oral administration. With immediate-release preparations, effects are noted within 2 to 3 hours of oral administration. Effects of sustained-release preparations may be delayed 6 to 8 hours and are reported as long as 15 hours after ingestion. CCAs are 80% to 98% protein-bound, have a moderate

volume of distribution (1.4 to 4.3 L/kg), are extensively metabolized by the liver, and are excreted in the urine and bile. Verapamil, diltiazem, and bepridil have active metabolites.

The CCA toxicology experience is based primarily on four agents: Verapamil, diltiazem, nifedipine, and amlodipine. Nicardipine, felodipine, nisoldipine, isradipine, and nimodipine are members of the same class as nifedipine and amlodipine (dihydropyridines) and have similar toxicity. Clevidipine, approved in 2008, is an intravenous short-acting dihydropyridine. Bepridil is a unique agent, with sodium and potassium channel antagonism in addition to CCA effects. Toxic CV effects of CCAs are in large part an exaggeration of their therapeutic effects. However, with overdose, the drug-specific effects noted in Table 324.1 are often lost (1). Though peripheral vascular resistance is always decreased, cardiac output may be normal, increased, or decreased. As only nimodipine penetrates the blood–brain barrier, central nervous system (CNS) effects are essentially due to hypoperfusion. Both hypoperfusion and impaired carbohydrate metabolism may lead to acidosis and ketosis. Impaired calcium-dependent insulin release and peripheral insulin resistance may cause hyperglycemia (2). This combination may lead to a diabetic ketoacidosis-like picture.

CCAs are considered so toxic that “one pill can kill” in the pediatric population. Death has been reported in a child after ingestion of a single tablet of nifedipine. The elderly are susceptible to toxicity at lower doses (3). Toxicity can also be seen when taken in therapeutic doses with other myocardial depressants, such as β-adrenergic antagonists and quinidine-like agents.

CLINICAL PRESENTATION

Signs and symptoms of toxicity include hypotension and bradycardia, but reflex tachycardia has been reported, especially with dihydropyridine ingestion. Inadequate perfusion may result in myocardial, cerebral, renal, and bowel ischemia or infarction. In severe cases, coma, seizures, and respiratory distress associated with cardiogenic and noncardiogenic pulmonary edema are described.

Toxic effects typically last 24 to 36 hours but may be longer with bepridil, amlodipine, and sustained-release preparations.

DIFFERENTIAL DIAGNOSIS

Myocardial infarction and overdose of β-adrenergic antagonists, cardiac glycosides, clonidine, guanabenz, imidazolines, angiotensin converting enzyme inhibitors, cholinergic agents (nicotine, organophosphate and carbamate insecticides, and agents to treat myasthenia gravis), tricyclic antidepressants (TCAs), alpha-methyldopa, and veratrum alkaloids may present similarly to those with CCA ingestion.

β-Adrenergic blocking agents are more likely to cause hypoglycemia, and CCAs are more likely to cause hyperglycemia. With cholinergic agents, salivation, nausea, vomiting, diarrhea, and weakness dominate the presentation. TCA toxicity infrequently presents with heart block and bradycardia. Although both TCA and CCA ingestions may result in prolonged QRS complexes (the latter as a result of ventricular escape rhythms), TCA-intoxicated patients often manifest evidence of antimuscarinic toxidrome and CNS depression in normotensive or hypertensive patients (see Chapter 339, “Cyclic Antidepressants”).

ED EVALUATION

The history should include time of ingestion and identification of other substances ingested or available to the patient. Physical examination should focus on cardiopulmonary and CNS status. Continuous peripheral and pulmonary artery pressure monitoring may be necessary in patients with hemodynamic compromise.

Laboratory abnormalities are nonspecific and may include metabolic acidosis and hyperglycemia. Serum drug levels are not readily available and are not useful in the management of these patients. The electrocardiogram (ECG) often shows decreased rate and first-, second-, or even third-degree AV block and may have changes indicative of ischemia or infarction (Fig. 324.1) (3). QT-prolongation and torsades de pointes may be noted with bepridil ingestion. Chest radiography may show pulmonary edema.

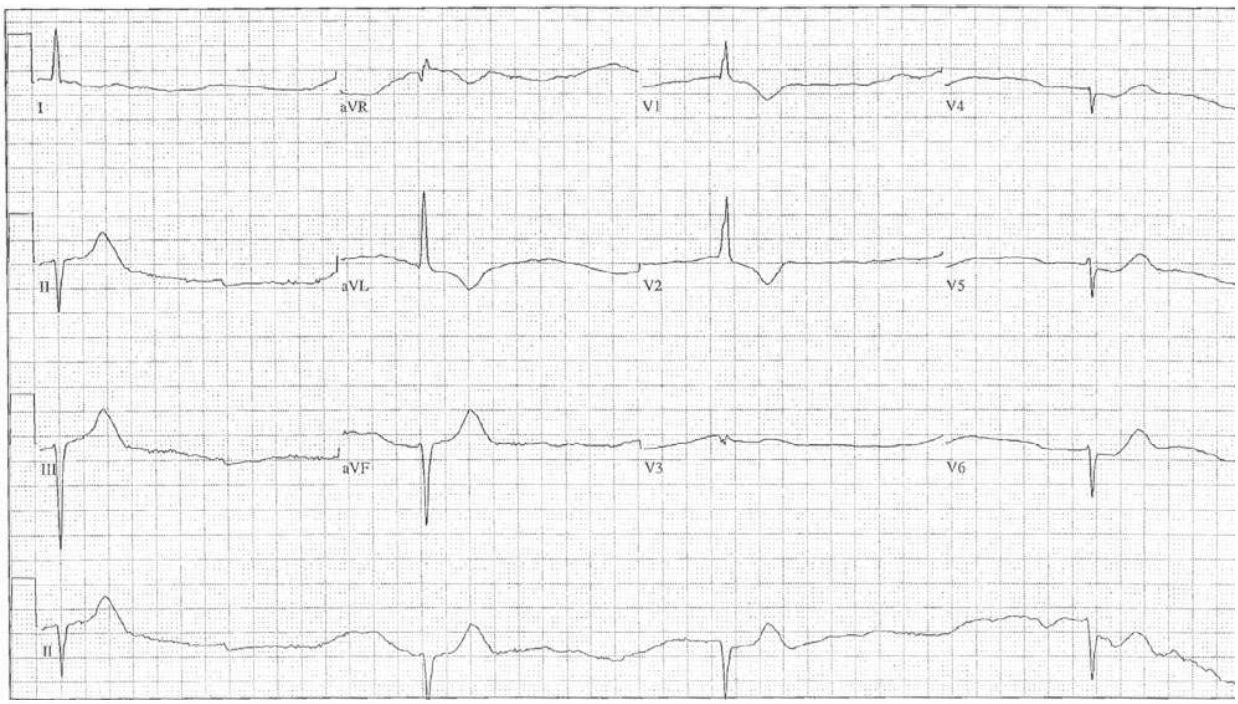

FIGURE 324.1 Initial electrocardiogram of a patient presenting after sustained-release verapamil ingestion. Findings include complete heart block with severe bradycardia and repolarization abnormalities.

KEY TESTING

- ECG and cardiac monitoring
- CXR for pulmonary edema
- No drug levels are useful; routine laboratory studies might be helpful for general supportive care

ED MANAGEMENT

Supportive care, activated charcoal, and advanced life-support measures should be initiated as necessary. Intravenous access should be established in all patients. Whole-bowel irrigation (WBI) is recommended for ingestions of sustained-release preparations, especially in patients presenting early. Smooth muscle relaxation may result in an ileus, limiting the utility of WBI. Mild hypotension may respond to a fluid challenge with 1 to 2 L of saline solution (10 to 20 mL/kg in children). When bradycardia, with or without AV

block, is also present, atropine (1.0 mg IV, 0.02 mg/kg in children) can be tried. Response is infrequent but may be improved after calcium administration (3). Patients with hypotension and concomitant symptomatic bradycardia or conduction defects should receive either calcium chloride (1 g IV slow push; 10 to 20 mg/kg in children) or calcium gluconate (3 g IV slow push; 30 to 60 mg/kg in children). This dose may be repeated every 5 to 15 minutes up to three times in patients who show incomplete, transient, or absent response (4). Calcium chloride extravasation can result in severe tissue damage, so limit calcium chloride use to central venous administration whenever possible. Owing to the short-lived effects of intravenous calcium, a continuous infusion at a rate of 0.2 to 0.4 cc/kg/hr (10% calcium chloride) or 0.6 to 1.2 cc/kg/hr (10% calcium gluconate) may be used to support heart rate and blood pressure in patients who respond to an initial bolus (5). Although calcium is frequently ineffective, proponents argue that this is a result of inadequate dosing. Doubling of serum calcium concentration was associated with significant hemodynamic improvement in both animal models and human cases. An ionized calcium concentration of 2 mmol/L has been suggested as a target level (6).

No single pressor agent has been consistently effective. Dopamine, dobutamine, norepinephrine, isoproterenol, alone or in combination, have been used with mixed success. Glucagon may also be of benefit for hypotension, but it should not be used until the effects of traditional pressors are optimized. Acidemia must be corrected, as it impairs the function of L-type VOCCs, enhances the toxic effects of some agents (e.g., verapamil), and decreases the efficacy of calcium. A swine model of verapamil toxicity demonstrated improved myocardial contractility and cardiac output with sodium bicarbonate administration (7).

The pharmacologic management of patients who fail to respond to these therapies remains controversial. Although strong evidence-based data are lacking, most toxicologists advocate the early, aggressive use of hyperinsulinemia-euglycemia (HIE) therapy in patients who show an inadequate response after initial fluid

resuscitation, atropine, and calcium administration. Insulin, used as part of HIE therapy, improves hemodynamics and survival and has reversed catecholamine-unresponsive shock in both animals and in case reports (5,8,9). Insulin has positive inotropic effects in conditions of myocardial stress without increasing myocardial oxygenation demand. During myocardial stress, the metabolism of myocardial cells is shifted away from fatty acid oxidation, toward carbohydrate dependence, improving the efficiency of energy biomechanics. In cases of severe CCA toxicity, hyperglycemia is frequently noted. The etiology is multifactorial, reflecting both impaired insulin release and peripheral resistance (2). The net result is that the CCA-intoxicated myocardium is further impaired secondary to limited cellular glucose uptake at a time of glucose dependence and subsequent transition back to less-desirable fatty acid metabolism. HIE is believed to reverse this impaired energy utilization state and improve myocardial glucose utilization. HIE also likely increases intracellular calcium concentrations, although this may cause only a small improvement. The failure of catecholamines and glucagon, despite initial transient improvement, may reflect catecholamine-induced increased myocardial oxygen demand and promotion of fatty acid metabolism and ketosis (5).

Although studied dosages have varied, a reasonable approach to HIE therapy is an initial intravenous bolus of 1 IU/kg regular insulin, followed by an infusion of 1 to 10 IU/kg/hr, titrated to clinical effect (systolic BP $>$90 mm Hg, HR $>$50/min) (8,9). Patients with serum glucose levels $<$200 mg/dL should receive one 50-mL ampule of 50% dextrose (0.25 g/kg in children) followed by frequent glucose measurements and supplemental glucose as required. Owing to potential insulin–mediated effects on serum potassium, patients with serum potassium concentrations $<$2.5 mEq/L should receive 40 mEq of potassium (1 mEq/kg in children; maximum, 20 to 40 mEq/dose) as an oral supplement or IV potassium, 10 to 20 mEq (0.10 to 0.30 mEq/kg in children) administered over the course of 1 hour. Serum glucose and potassium concentrations should be regularly monitored during HIE therapy, and for up to 24 hours following discontinuation.

More recently, the successful use of intravenous fat emulsion (IFE) has been reported in the management of CCA intoxication (10), especially for the more lipophilic agent verapamil. It has been suggested that IFE works at least in part by sequestering lipophilic agents, thereby decreasing distribution to target tissues and redistributing the toxic agent from the tissue into the IFE lipid medium. While controversial in the setting of CCA toxicity, current IFE dosage recommendations for the management of local anesthetic toxicity are a 1.5 mL/kg bolus of 20% IFE followed by an infusion of 0.25 to 0.50 mL/kg/min 20% IFE until hemodynamic stability. IFE use has been associated with fat emboli syndrome and is contraindicated in the setting of acute myocardial infarction, known disorders of fatty acid metabolism and egg allergy. Concern also exists for the potential of IFE as a nonspecific sequestering agent to sequester concomitantly administered antidotes.

Hemodynamically significant bradycardia or heart block unresponsive to medical therapy may require pacemaker placement. Electrical capture occurs in only 50% of patients (Fig. 324.2) (3). Heart rate was improved more than blood pressure. In hypotensive patients unresponsive to pharmacologic therapies, intra-aortic balloon counterpulsation and cardiopulmonary bypass have been successfully employed. The specific role of enhanced elimination, other than through gastrointestinal decontamination, has not been clearly defined. Based upon pharmacokinetic properties, conventional extracorporeal elimination would be expected to be of limited effectiveness. Several reports have documented the successful use of albumin dialysis with the Molecular Adsorbents Recirculating System (MARS) (1). Full recovery can be expected unless prolonged shock has resulted in irreversible end-organ damage.

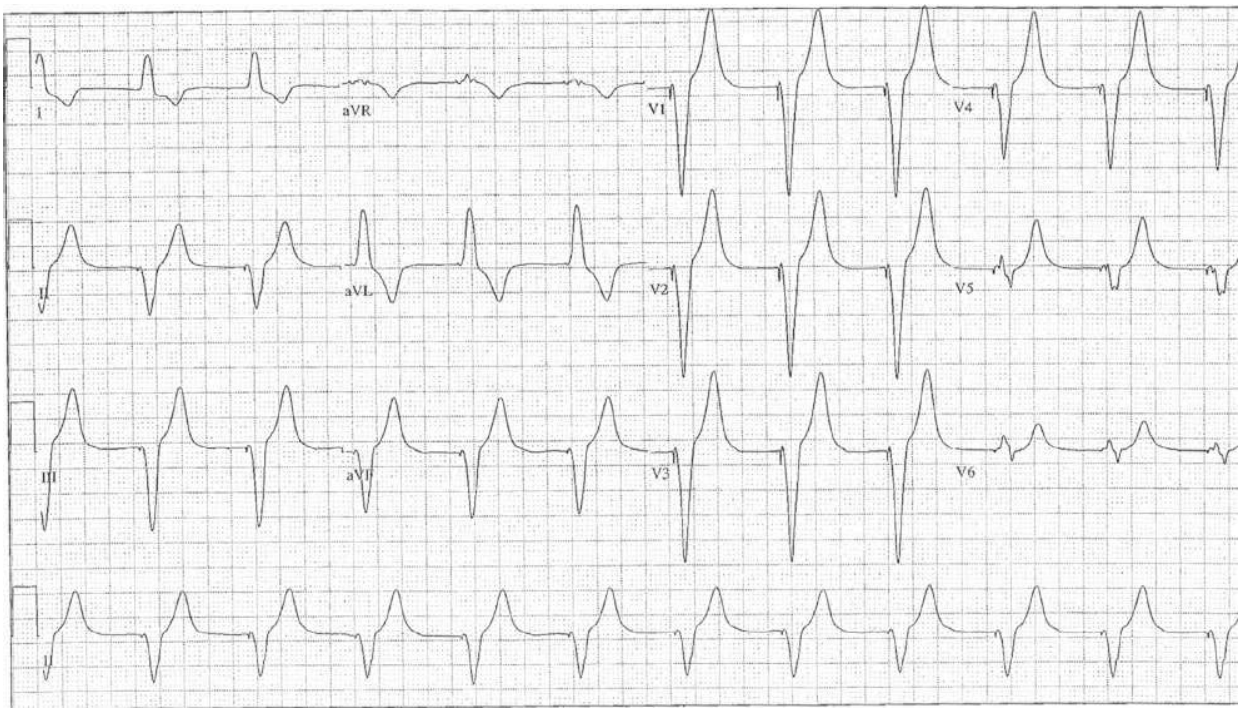

FIGURE 324.2 Follow-up electrocardiogram after emergent transvenous pacemaker placement. Note that electrical capture occurs in only 50% of patients and that blood pressure may not improve despite increased heart rate.

CRITICAL INTERVENTIONS

- Admit or observe asymptomatic patients with overdoses of sustained preparations for an extended period of time.
- Administer IV fluids, calcium, and atropine for hypotension and bradycardia.
- Initiate HIE therapy for hypotension unresponsive to fluids and calcium.
- Consider the use of IFE, especially in toxicity caused by more lipophilic agents.
- High doses of calcium may be needed for a clinical response.
- Owing to lack of consistently effective therapeutic interventions, early aggressive gastrointestinal decontamination is recommended.

DISPOSITION

Asymptomatic patients should be observed for 4 to 6 hours after ingestion of standard formulations and 18 to 24 hours after ingestion of sustained-release ones. Those who remain asymptomatic may be discharged or referred for psychiatric evaluation. Symptomatic patients should be admitted to an intensive care unit. Transfer may be necessary if an intensive care unit bed is unavailable and should be arranged as soon as the ingestion is recognized, because CV performance may rapidly deteriorate. The patient should be transferred in an advanced life-support unit with an adequate supply of CV drugs on hand. A regional poison center or a toxicologist should be consulted if the physician is unfamiliar with the management of CCA overdose.

Common Pitfalls

- Failure to consider CCA poisoning in patients with hypotension, bradycardia, or AV block, particularly when hyperglycemia is present.
- Failure to appreciate that ingestion of a single pill may be lethal in a toddler.
- Failure to consider whole-bowel irrigation and multiple-dose charcoal for patients with overdoses of sustained preparations.
- Failure to initiate aggressive HIE therapy in a timely manner.

CHAPTER 325

Cardiac Glycosides

John S. Kashani

Cardiac glycosides (CGs) are a closely related group of chemicals having a common effect on the myocardium. CGs are found in a variety of plants, including oleander, foxglove, red squill, and lily of the valley, and in the skin, salivary glands, and venom glands of *Bufo* genus toads (Table 325.1). CGs have also been found in some herbal preparations, sometimes as an unintentional ingredient resulting from the misidentification of plants (1). The term *digitalis* is often used as a generic term referring to any substance containing CGs. Digoxin (Lanoxin, Digoxin, Digitek) is the only approved CG in the United States and is used for congestive heart failure, atrial fibrillation, atrial flutter, and paroxysmal atrial tachycardia. CGs are also being investigated as antineoplastic agents for the treatment of various cancers (2).

TABLE 325.1
Sources of Cardiac Glycosides

Genus and Species	Common Name	Part Used
Digitalis purpurea	Purple foxglove	Leaf
Digitalis lanata	Grecian foxglove	Leaf
Strophanthus kombé		Seed
Strophanthus gratis		Seed
Urginea maritima (squill)	Sea onion	Bulb
Nerium oleander	Oleander	All parts
Thevetia neriifolia	Yellow oleander	All parts
Convallaria majalis	Lily of the valley	All parts
Bufo sp	Toad	Skin

CGs inhibit the sodium potassium adenosine triphosphatase (ATPase) membrane pump in cardiac cells. Normally, depolarization follows the opening of the fast sodium channels. The rise in the intracellular potential opens voltage-gated calcium channels, causing the influx of calcium. The rise in intracellular calcium causes further calcium release from the sarcoplasmic reticulum, producing contraction. In the presence of CGs, the sodium potassium ATPase is inhibited, causing an increase in intracellular sodium which disrupts the sodium calcium counterexchange, raising intracellular calcium levels. The increase in intracellular calcium promotes interaction between actin and myosin, resulting in an increased inotropic effect. In addition to the inotropic effects, CGs increase automaticity, shorten the time for repolarization of the atria and ventricles, slow conduction through the sinoatrial (SA) and atrioventricular (AV) node, and increase vagal parasympathetic tone.

The therapeutic daily dose of digoxin ranges from about 0.005 mg/kg in premature infants to as much as 0.75 mg in adults. Digoxin is 40% to 90% intestinally absorbed, with an onset of action from 1.5 to 6 hours. The actual volume of distribution ranges from 4 to 7 L/kg in adults and 10 to 16 L/kg in children. Digoxin is 25% protein-bound, predominantly renally eliminated with a half-life upward of 1.6 days. Dosing adjustment is based on creatinine clearance, and with a decrease in the dose and frequency for renal failure patients. Therapeutic serum digoxin levels are 0.5 to 2.0 ng/mL but a serum concentration $>$2.0 ng/mL measured at least 6 hours postingestion may indicate CG toxicity. High blood levels occur early after ingestion, before the drug has had time to distribute to tissues. After an acute ingestion, before distribution occurs, a level will only verify that ingestion has occurred but does not predict the degree of clinical toxicity (3).

Ingestion of oleander or Bufo toxins can result in a false-positive digoxin level as a result of the partial cross-reactivity in the assay, but the measured digoxin levels do not correlate with toxicity. Other nondigoxin CGs may or may not cross react with digoxin immunoassays. A source of false-positive digoxin levels are

substances called endogenous digoxin-like steroidal substances (EDLS). These substances may be present in patients with renal insufficiency, hepatic disease, hypertension, agonal states, pregnancy, cor pulmonale, myocardial infarction, mucocutaneous lymph node syndrome, subarachnoid hemorrhage, or congestive heart failure and in both premature and full-term infants (4). Levels are usually low but have occasionally been measured >2.0 ng/mL.

Electrocardiogram (ECG) changes occur frequently but it is important to understand that, in the absence of significant dysrhythmias, ECG changes only indicate the presence of digoxin and do not correlate with toxicity. The "digitalis effect" refers to four typical ECG findings which can be seen at therapeutic levels. The earliest finding includes T-wave abnormalities, with inversion or elevation that may mimic acute ischemia or pericarditis. Peaking of the terminal of the T wave may occur. The second finding is a shortened QT interval. The third finding is scooping or sagging of the ST segment with concomitant ST-segment depression (more pronounced in the lateral leads). Finally, there may be an increase in the U-wave amplitude.

Digoxin toxicity is the result of exaggerated therapeutic effects. Ectopy results from increased automaticity. Bradycardia and AV blocks result from depressed cardiac conduction. Ventricular tachycardia (VT) in the setting of CG toxicity has a 50% mortality rate. Risk factors associated with a poor prognosis include advanced age, heart disease, male sex, high-degree AV block, and hyperkalemia (5). The coadministration of P-glycoprotein inhibitors may result in an increased digoxin level and toxicity (6). Many other factors are known to contribute or predispose to toxicity (Table 325.2).

TABLE 325.2
Conditions Contributing to Digoxin Toxicity

Advanced age
Renal impairment
Hypoxia
Myocardial ischemia
Hypothyroidism
Hypokalemia
Hypomagnesemia
Hypercalcemia

CLINICAL PRESENTATION

Toxicity in the acute or chronic setting present differently. Acute toxicity occurs most often in a younger population as an accidental or intentional ingestion. In healthy adults, single acute doses of <5 mg of digoxin seldom cause toxicity. Chronic toxicity usually occurs in the elderly. Because of the narrow therapeutic range of digoxin, toxicity can occur with only two to three times the therapeutic dose in patients on chronic therapy.

Patients with acute digoxin toxicity will often present with nausea and vomiting. Chronic toxicity is more likely to present with central nervous system (CNS) findings, including confusion, lethargy, depression, fatigue, headache, paresthesias, weakness, scotomata, and disturbances of color vision, especially xanthopsia (yellow vision).

Virtually any dysrhythmia may develop as a result of toxicity, although rapid atrial fibrillation or atrial flutter is rare (see Table 325.3). PVCs, either unifocal or multifocal, are most common. The three classically described dysrhythmias include (1) paroxysmal atrial tachycardia with block (considered to be pathognomonic of digitalis toxicity), (2) junctional (AV-nodal) tachycardia, and (3) VT. The presence of any tachydysrhythmia with block (e.g., paroxysmal atrial tachycardia with block, atrial fibrillation with a regular ventricular response as a result of AV block with a junctional escape rhythm) is highly suggestive of CG toxicity. Any slowing of the ventricular response to atrial fibrillation in a patient on digoxin may suggest toxicity. AV-conduction blocks from first degree to third degree may occur, although Mobitz type II is rare. Sinus

bradycardia, from increased vagal tone, and other bradydysrhythmias are common. Hypotension suggests a hemodynamically significant dysrhythmia, loss of vasomotor regulation, or the presence of coingestant(s).

TABLE 325.3
Common Digitalis-Induced Dysrhythmias

Bradyarrhythmias	Tachyarrhythmias
Sinus exit block or sinus arrest	Atrial tachycardia with block
Sinus bradycardia	Junctional tachycardia
Atrioventricular nodal block first degree; second-degree type 1; third degree	Ventricular premature beats ventricular tachycardia especially bidirectional
	Ventricular fibrillation

After acute overdose, the most common ECG abnormalities are sinus bradycardia and varying degrees of AV block; ventricular dysrhythmias are less frequently seen. Chronic intoxication is more commonly associated with ventricular dysrhythmias, atrial tachycardia, and junctional tachycardia. Hyperkalemia is common after acute overdose whereas hypokalemia, probably related to concurrent diuretic use, is more common in chronic poisoning.

DIFFERENTIAL DIAGNOSIS

Intoxications that can cause CG-like bradydysrhythmias include those from class 1B antidysrhythmics, baclofen, β-adrenergic blockers, calcium channel antagonists, cholinergic agonists, cholinesterase inhibitors, clonidine, guanabenz, ingested imidazoline decongestants, and nicotine. CG-like tachydysrhythmias can be caused by poisoning with class 1A, class IC, and class III antidysrhythmics, antihistamines, baclofen, cyclic antidepressants, fluoride, heavy metals, local anesthetics, meperidine, neuroleptics, propoxyphene, quinine and related antimalarials, and sympathomimetics. Plants causing similar cardiotoxicity include *Phoradendron tomentosum* (American mistletoe), *Remijia* sp, *Rhododendron* sp, *Schoenocaulon officinalis* (sabadilla), *Stylophorum*

diphyllun, Veratrum sp (e.g., American hellebore), and *Zanthoxylum brachycanthum.* Worsening cardiomyopathy, congestive heart failure, CNS hemorrhage/ischemia, electrolyte abnormalities, myocardial ischemia/infarction, myocarditis, pericarditis, pheochromocytoma, pre-excitation syndromes, and thyroid dysfunction should also be considered in the differential diagnosis of CG-like cardiotoxicity.

Intoxications that can cause CG-like visual disturbances include carbon disulfide, ergot alkaloids, ethambutol, heavy metals, methanol, quinine and antimalarials, salicylates, and tamoxifen. The differential diagnosis of visual disturbances includes diseases such as cataracts, cerebrovascular disease, corneal disease, diabetes, glaucoma, macular degeneration, migraine, optic neuritis, retinal detachment, vasculitis, and vitreous hemorrhage.

ED EVALUATION

The history should include the amount, route, duration, and intent of exposure. Because CGs may be present in herbal supplements, the medication history should include herbal supplement use. The patient should be specifically examined for signs consistent with congestive heart failure and decreased peripheral perfusion. The patient should be placed on continuous cardiac monitoring, and a 12-lead ECG should be obtained. Routine laboratory studies include serum electrolytes, calcium, magnesium, blood urea nitrogen, and serum creatinine. Digoxin levels and potassium levels can be checked every 3 to 4 hours after an acute ingestion. A chest radiograph should be obtained in patients with cardiac dysrhythmias, hypotension, underlying cardiac disease, or hypoxia.

KEY TESTING

- ECG should be done quickly.
- Serum digoxin and potassium levels should be checked and followed until stable.
- An elevated creatinine slows digitalis excretion and may increase length of toxicity.
- Other routine laboratories consistent with supportive care.

ED MANAGEMENT

Advanced cardiac life support (ACLS) measures should be instituted as necessary. Intubation should be considered in patients with an altered mental status. Acid–base abnormalities, hypoxia, fluid, and electrolyte imbalances should be corrected. Although hypokalemia can exacerbate digoxin toxicity, caution is advised when replacing potassium in patients with renal failure. It is traditionally taught that the administration of (IV) calcium in the setting of digoxin toxicity can lead to potentially fatal dysrhythmias. There is no objective human evidence to support this concept, and calcium has been administered in patients with hyperkalemia and digoxin toxicity without complication (7). However, hyperkalemia in the setting of acute digoxin responds well to Digibind and as such, it should be considered a first-line agent. IV sodium bicarbonate, inhaled β-adrenergic agonists, insulin, and glucose can be used to treat hyperkalemia in the setting of hyperkalemia and digoxin toxicity. Because hyperkalemia reflects transmembrane shifts, and not total body overload, exchange resins that deplete potassium are of no benefit. Digoxin Fab antibody fragments correct the hyperkalemia from acute CG poisoning.

While activated charcoal decreases drug absorption, there are no well-designed human studies that show actual clinical benefit when activated charcoal is administered to a poisoned patient. The position of the American Academy of Clinical Toxicology is that activated charcoal should not be routinely used in the treatment of poisoned patients, but it may have a benefit if given within 1 hour of a drug that is known to be adsorbed to activated charcoal (8). Antidigoxin Fab antibody fragments should be used for hemodynamic compromise, life-threatening bradydysrhythmias and tachydysrhythmias and for hyperkalemia (serum potassium $\leq$5.5 mEq/L) after an acute overdose (5). Although an elevated serum-digoxin level confirms an overdose, it should not guide the use of Fab fragments and there is no known benefit of prophylactic administration of Fab fragments.

Digoxin Fab fragments are prepared by immunizing sheep, purifying their antibodies, and cleaving off the Fc fragments with papain. Those patients with a history of allergy to sheep or papaya may be at risk for an allergic reaction. The two antibody preparations commercially available, Digibind (Glaxo Wellcome) and DigiFab (Protherics Inc.), are virtually identical therapeutically. Antibody fragments possess a greater affinity for digoxin than sodium potassium ATPase and lower the extracellular unbound digoxin concentration. Further equilibration of receptor-bound digoxin with the extracellular fluid leads to a rapid release of digoxin from its receptor sites. The drug-antibody complex is renally excreted, with a half-life of 16 hours in normal renal function and up to 4 days in patients with renal failure.

If the quantity of digoxin ingested is known, the dose (in vials) of DigiBind or DigiFab can be calculated. The ingested dose in milligrams is divided by 0.6 mg/vial. Each vial of DigiBind contains 38 mg of Fab fragments, which will bind 0.5 mg of digoxin, although each vial of DigiFab contains 40 mg of Fab fragments. A typical dose for acute overdose is 5 to 10 vials. In chronic toxicity, the body load in milligrams can be estimated by multiplying the steady state serum concentration of digoxin by 5.6 times the patient's weight in kilograms divided by 1,000. The usual dose of Fab fragments in the setting of chronic toxicity is one to two vials. Digoxin Fab antibody fragments are given IV over 30 minutes unless the patient is in cardiac arrest, when it should be given as a bolus. Resolution of the digoxin-induced dysrhythmias and hyperkalemia are usually noted within 30 minutes of Fab-fragment administration, but it may take several hours for a maximal effect. The only proven beneficial treatment for symptomatic yellow oleander poisoning is digoxin-specific antibody fragments (9). In the setting of CG toxicity secondary to oleander or bufo toxins, larger doses of Fab fragments may be required, because of weak cross-reactivity.

Because serum digoxin assays measure both protein-bound and unbound drug, the serum digoxin level will rise after administration of antidigoxin Fab fragments as the drug is pulled from the tissues and is sequestered with the antibody in the serum. Free digoxin

levels, measured by equilibrium dialysis or ultrafiltration, will be low if the proper amount of Fab-fragment drug is given. A rebound rise in serum digoxin levels within 24 hours of antibody administration is seen in patients with normal renal function and may be seen in up to 8 days in patients with renal failure. This rise is presumably as a result of metabolic degradation of the antigen-antibody complex. Recurrent clinical toxicity is rare.

Other treatment may be necessary if digoxin Fab fragments are unavailable, while waiting for an effect, and when antibody therapy is unsuccessful. Atropine (0.5 mg IV) can be given for bradydysrhythmias. Since Fab fragments are more effective and safer, pacing should not delay antibody therapy. Irritation by the pacing wire in a digoxin-poisoned heart can precipitate ventricular tachydysrhythmias. Therapy for CG-induced ventricular tachydysrhythmias may include IV phenytoin (25 mg/min until a desired effect or a total of 15 mg/kg has been given), lidocaine (1 mg/kg), and magnesium sulfate (2 to 3 g IV in 1 minute). Refractory cardiac tachydysrhythmias induced by digoxin may respond to magnesium infusions (10). Pulseless rhythms require defibrillation or cardioversion. Cardioversion may precipitate ventricular fibrillation. If possible, medical management should be used initially. When cardioversion is necessary, initial settings should be at reduced power settings (5 to 10 J).

CRITICAL INTERVENTIONS

- Administer digoxin Fab antibody fragments for hemodynamically compromising or potential lethal dysrhythmias and for hyperkalemia (K $>$5.5 mEq/L) after acute overdose.
- Avoid using calcium and exchange resins to treat hyperkalemia.
- Begin with low power settings when cardioverting digoxin-induced tachydysrhythmias.

DISPOSITION

Intensive care unit admission is advised for patients with acute symptoms or who have elevated digoxin levels and dysrhythmias.

Chronically poisoned patients that are hemodynamically stable and do not require active treatment may be observed on a telemetry unit. If Fab fragments or pacemaker therapy is not available, the patient should be transferred by ACLS personnel to the nearest facility that has these modalities or the Fab fragments can be transported to the hospital. Poison centers and hospital pharmacies are often aware of the institutions with Fab fragments.

Common Pitfalls

- Failure to consider plant products such as herbals or teas in the differential diagnosis of CG-like cardiotoxicity.
- Failure to appreciate that toxicity is delayed up to 8 hours after acute ingestion.
- Failure to appreciate that digoxin assays may not yield a measurable digoxin level with ingestions of CGs from plants or Bufo toads.
- Failure to appreciate the differences between acute and chronic CG poisoning.
- Failure to appreciate that pacemaker wires can irritate the CG poisoned myocardium and precipitate ventricular tachydysrhythmias.

PART 7 • CHEMICALS, GASES, AND METALS

CHAPTER 326

Arsenic and Mercury

Beth A. Baker

Arsenic has been used as a poison throughout history. Potential sources of arsenic exposure include intentional poisoning, contaminated drinking water, rock and volcanic eruptions, arsine gas, gallium arsenide used in the computer and semiconductor industries, smelting of metals, and arsenic-containing wood preservatives. Elevated levels of arsenic are found in drinking water in many parts of the world; the largest arsenic water contamination event occurred in Bangladesh and West Bengal, India. Arsenic is found in the earth's crust primarily as inorganic arsenic and is a contaminant of a variety of metal ores. Seafood or shellfish may contain organic arsenic, which is considered to be nontoxic. The average dietary intake of arsenic is about 2 to 92 μg/d (4).

Arsenic is tasteless, odorless, and readily absorbed by the gastrointestinal (GI) tract and inhalation but is poorly absorbed through the skin. An ingestion of 100 to 200 mg of arsenic is potentially fatal. Arsenic exists as either the less toxic pentavalent (arsensate or As^{+5}), or the more toxic trivalent (arsenite or As^{+3}) form. The organic arsenic present in seafood is considered nontoxic and is cleared from the body within days. Arsenic trioxide is used to treat promyelocytic leukemia. Arsenic is an intracellular toxin that impairs cellular respiration by inhibiting more than 200 enzymes throughout the body (including the sulfhydryl group containing enzymes) and may substitute for phosphates in high-energy compounds. Arsenic is a known human carcinogen and is linked to increased rates of skin, lung, and other cancers.

Mercury is a protoplasmic poison that binds to sulfhydryl groups. It exists in three forms that each have a different toxicity: (a) elemental, (b) inorganic, and (c) organic. Elemental mercury is a mobile liquid at room temperature. Elemental mercury is poorly absorbed through intact skin or via ingestion (<1%) but readily volatilized and well absorbed via inhalation (50% to 80% absorbed) (6). The half-life of mercury in blood after a single exposure is approximately 3 days (6). Mercury is primarily excreted in the urine, and the urine half-life is 30 to 90 days (3). Inorganic mercury is primarily absorbed via the GI tract and is corrosive. Inorganic mercury does not enter the central nervous system (CNS) as well as elemental or organic mercury. Mercury is naturally present in the environment, but most of the atmospheric inorganic mercury is from manmade sources such as smelting, coal combustion, and incineration. Inorganic mercury is primarily excreted by the kidneys, but organic mercury is primarily excreted in feces. Atmospheric mercury if deposited in water may be transformed or methylated by microorganisms from inorganic to organic or toxic methylmercury. Mercury-contaminated fish is a concern throughout the world. Organic mercury or methylmercury bioaccumulates in the food chain. Large, predatory fish such as shark, swordfish, king mackerel, and tilefish have higher mercury levels than small fish (10). However, it is also found in shellfish and is well absorbed via the GI tract. Methylmercury is the type of organic mercury most commonly found in nature and bioaccumulates up the food chain. Organic mercury is well absorbed via ingestion. Some organic mercury compounds such as dimethylmercury are extremely toxic and are well absorbed through intact skin.

Mercury exposure may occur through dental amalgams, although most experts believe amalgams do not cause significant health effects. Mercury is also found in food or grain treated with mercury-containing fungicides, disc batteries, thimerosal (preservative that contains ethyl mercury), mercury thermometers, and dyes. Mercury is used in batteries, switches, and scientific equipment and as a chemical intermediate, fungicide, or catalyst. Though the American Academy of Pediatrics asked that thimerosal be removed from

childhood vaccines in 1998 because of concerns about autism, there is no proven causal association found between autism and thimerosal-containing vaccines, and many vaccines since 2001 contain no thimerosal (5).

CLINICAL PRESENTATION

Acute arsenic ingestion causes GI symptoms such as nausea, vomiting, abdominal pain, and "rice water" diarrhea within 10 minutes to several hours after exposure. Patients may also develop shock and pulmonary edema owing to capillary leakage, toxic hepatitis, rhabdomyolysis, GI ulcerative lesions, acute tubular necrosis, delirium seizures, coma, and death (5). Arsenic toxicity may cause cardiovascular instability, hypotension, intravascular volume depletion, myocardial dysfunction, a prolonged QT interval, and dysrhythmias.

Subacute or chronic symptoms from arsenic poisoning include anemia, leukopenia, aplastic anemia, and peripheral neuropathy. Arsenic-induced skin changes may include hyperpigmentation, hypopigmentation, hyperkeratosis, Bowen disease, squamous cell cancers, basal cell cancers, or Blackfoot disease (a form of arsenic-induced peripheral vascular disease resulting in gangrene). Mees lines (transverse white lines in the nails) occur in a minority of arsenic toxic patients. Neurologic problems caused by arsenic toxicity include peripheral neuropathies, fatigue, CNS depression, tremulousness, ataxia, and incoordination. Arsine gas is a colorless, nonirritating gas that causes a triad of abdominal pain, hematuria, and jaundice owing to massive hemolysis.

Subacute or chronic poisoning may present with CNS symptoms, skin changes, and GI or renal dysfunction. Symptoms include tremors, gingivitis, stomatitis, cheilitis, rash, headaches, choreoathetosis, weight loss, fatigue, and erethism, a syndrome that includes shyness, anxiety, emotional lability, irritability, and delirium.

Elemental mercury inhalation can cause symptoms within hours; these include cough, chills, fever, nausea, vomiting, diarrhea,

interstitial pneumonitis, bronchitis, and eventually lung fibrosis. Elemental mercury in the GI tract is unlikely to be absorbed and does not typically cause systemic effects unless it becomes trapped in the gut or if there is GI perforation (3). Intravenous or subcutaneous injection of mercury may result in abscess or granuloma formation at the injection site and systemic symptoms (Fig. 326.1) (1,8).

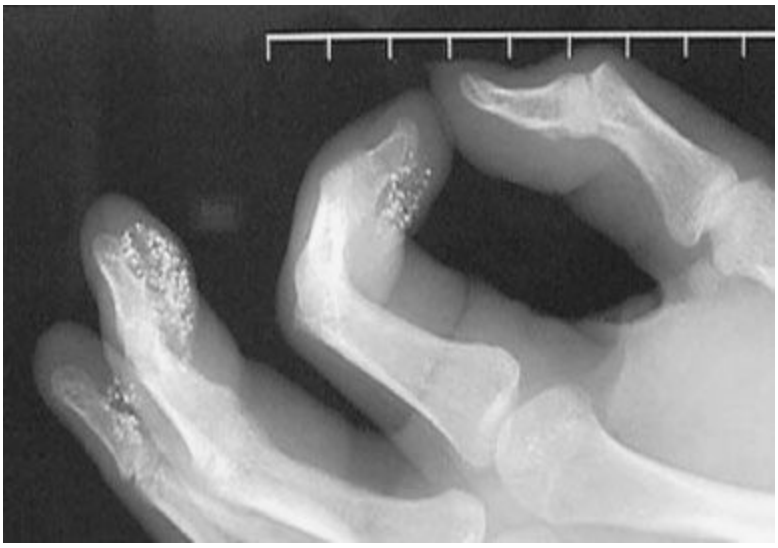

FIGURE 326.1 Multiple subcutaneous mercury deposits that were injected by patient.

Inorganic mercury salts such as those in mercury disc batteries, if ingested, causes irritant or caustic GI irritation, bloody diarrhea, abdominal pain, darkened and discolored oral mucosa, necrosis of the GI tract, hematochezia, hematemesis, circulatory collapse, acute tubular necrosis, and death. One to 4 g of mercuric chloride may be fatal in adults (11). Mercuric stomatitis, gingivitis, loosening of the teeth, jaw necrosis, and acute renal failure may occur. Inorganic arsenic causes skin and mucous membrane irritation.

Ingestion of organic or alkyl mercury causes primarily CNS symptoms such as paresthesias, tremor, ataxia, dysarthria, dementia, and tunnel vision. Acrodynia or pinks disease was originally reported in children and results in erythema and induration of the palms and soles along with systemic symptoms.

Maternal organic mercury exposure may cause cerebral palsy, mental retardation, blindness, seizures, cataracts, hearing loss, and CNS abnormalities in the fetus. Organic mercury crosses the placenta and is secreted in breast milk. The US Environmental Protection Agency and the Food and Drug Administration recommend pregnant women, women who might become pregnant, nursing mothers, and young children to not eat shark, swordfish, king mackerel, or tilefish, but they can eat up to 12 ounces (two average meals) a week of a variety of fish and shellfish that are lower in mercury (such as shrimp, canned light tuna, salmon) and check local advisories about the safety of fish caught by family or friends (10). Local fish may be tainted from nearby coal plants or incinerators.

DIFFERENTIAL DIAGNOSIS

Arsenic and mercury poisoning may present with GI symptoms and neurologic symptoms. Similar symptoms may occur with other heavy metals such as iron, lead, and thallium, and other toxins such as botulism, viral or bacterial infections, mushrooms, and other toxic agents such as organophosphates, ricin, lithium, alcohol, theophylline, antimetabolites, and colchicine.

Infectious gastroenteritis mimics the GI symptoms, but neurologic symptoms and long-lasting unexplained symptoms warrant suspicion.

ED EVALUATION

The initial evaluation should identify specific symptoms and the route of exposure and specific chemical or product that the patient was exposed to. Physical examination should include vital signs, cardiovascular, respiratory, and neurologic evaluations. The mouth and oral mucosa may show corrosive injury. Elemental mercury inhalation and acute arsenic poisoning may cause acute respiratory distress, and a chest x-ray is therefore appropriate. Abdominal x-ray may identify retained mercury or arsenic densities or ingested disc batteries. Electrocardiograph (ECG) monitoring to detect prolonged

QT and arrhythmias is appropriate for significant arsenic toxicity. Additional studies may be needed, including complete blood count (arsenic, arsine gas), arterial blood gas or oxygen saturation (elemental mercury, arsenic), serum electrolytes, blood urea nitrogen, Cr, glucose, liver function tests, and creatine kinase (CK) (severe mercury or arsenic poisoning).

Arsenic levels may be measured in blood, urine, hair, or nails. Blood arsenic is cleared within hours and is of little value. Urinary arsenic is the most reliable indicator of recent inorganic arsenic exposure. Twenty-four-hour urine arsenic is most commonly used but, if necessary, a spot urine arsenic corrected for creatinine concentration can be collected in the emergency department (ED) prior to chelation. Normal urine arsenic levels may vary from laboratory to laboratory but are usually <50 μg/L or <50 μg/g creatinine (2). Organic arsenic from seafood or shellfish ingestion may cause an elevated urine arsenic level for several days up to 2,000 μg/L, but it is relatively nontoxic and is rapidly cleared from the body. If organic arsenic is suspected, the laboratory can speciate the arsenic to determine whether the elevated level is due to organic or the more toxic inorganic arsenic. Urine arsenic elimination has three phases: First-phase half-life is 2 days (65% of dose), second-phase half-life is 10 days (30% of dose), and third-phase half-life is 40 days (4% of dose) (9). Arsenic levels may also be assessed in hair or nails, which may better reflect chronic arsenic toxicity. Hair levels, however, may reflect external contamination from water, sweat, or airborne arsenic and not internal contamination.

Typically whole blood mercury level is <10 μg/dL, but only a level >25 μg/dL requires treatment. Normal 24-hour urine mercury level is <20 μg/dL; levels >150 μg/dL require treatment. Urine mercury may correlate with inorganic mercury toxicity but may not be as useful for methylmercury or organic mercury toxicity. A blood mercury level is recommended for methylmercury or organic mercury toxicity. Elevated urine or blood mercury levels may occur after seafood or fish consumption. Mercury may also be measured in hair, but organic mercury is not detected in hair.

KEY TESTING

Arsenic

- EKG if acute cardiac symptoms
- Spot urine arsenic or 24-hour urine arsenic
- CBC, Hb in arsine gas
- Abdominal x-ray if ingested, CXR if respiratory symptoms

Mercury

- Abdominal x-ray if ingested, CXR if respiratory symptoms
- Blood mercury (better for organic mercury)
- Spot urine mercury or 24-hour urine mercury

ED MANAGEMENT

Acute arsenic or mercury poisoning may be life-threatening, and advanced life-support measures may be required. The primary treatment for arsenic and mercury toxicity is supportive care and removal of the patient from further exposure. Urine arsenic levels or blood or urine mercury levels can be collected in the ED, but results are not available for several days. Aggressive intravenous fluid resuscitation may be needed with large ingestions of arsenic or inorganic mercury salts or arsine gas exposure. With arsenic, it is important to maintain potassium, magnesium, and calcium concentrations within normal ranges and to avoid use of drugs that would prolong the QT interval.

Acute inhalation of mercury vapor may result in life-threatening respiratory failure, and ventilatory support may be needed. Patients exposed to arsine gas should have dermal decontamination. Both arsenic and mercury adsorb poorly to activated charcoal. Whole-bowel irrigation can be helpful if abdominal x-rays show persistent radiopaque material in the GI tract (8).

If there are concerns about corrosive lesions or ulcers after inorganic mercury ingestion, upper GI endoscopy should be considered before lavage and whole-bowel irrigation are performed. Inorganic mercury salt ingestion may result in severe gastroenteritis with third-spacing and cardiovascular collapse. As the most likely cause of death after ingestion of inorganic mercury salts is renal

failure, aggressive fluid therapy to maintain renal perfusion may be helpful. Arsenic and mercury levels will usually fall to normal range within several weeks to months if the patient is removed from further exposure (7). Chelation therapy is recommended only for patients with significant symptoms or extremely high arsenic or mercury levels (4,8). Patients who are severely ill with known or high suspicion of acute arsenic or mercury poisoning can be chelated after a spot urine arsenic or spot urine mercury or blood mercury is collected. Dimercaprol or British anti-Lewisite (BAL) can be given as a 3- to 5-mg/kg IM injection every 4 to 6 hours for severely arsenic-poisoned patients, but there is evidence from animal studies that BAL may shift arsenic or mercury into the brain (2). Patients with significant symptoms from inorganic mercury poisoning can be treated with BAL—5 mg/kg/dose every 4 hours IM for 48 hours, then 2.5 mg/kg every 6 hours for 48 hours, then 2.5 mg/kg every 12 hours for 7 days (8).

DMSA, or 2, 3-dimercaptosuccinic acid, is a more effective derivative of BAL that is an oral chelator if the patient can tolerate oral medication. Oral DMSA is the preferred chelator for organic mercury poisoning and for mercury poisoning if the patient has normal renal function and is not severely ill (8). BAL may be contraindicated with methylmercury (7). The usual dose for DMSA is 10 mg/kg tid for 5 days, then bid for 14 days. Use of DMSA is off-label as DMSA is approved by the FDA only for treatment of lead poisoning or mercury poisoning in children. DMPS has been shown to effectively chelate arsenic or mercury but is not approved for clinical use by the FDA. Chelation with intramuscular BAL is appropriate for patients with significant GI toxicity who are unable to take oral meds and may be started if there is a high level of clinical suspicion even before the blood or urine levels are available. BAL and DMSA are both renally excreted and should be used with caution in patients with renal impairment. Chelating agents should be used in pregnancy only if a patient is extremely ill.

Patients who have injected elemental mercury subcutaneously or IV should have x-rays of the affected sites (1). Large amounts of retained subcutaneous mercury should be surgically removed to

prevent granulomas and skin necrosis (1,8). Hemolysis due to arsine gas exposure may respond to exchange transfusions or blood transfusions and does not respond to BAL chelation.

For spills of elemental mercury, appropriate clean-up measures include use of a high efficiency particulate air filter vacuum cleaner and a decontamination kit instead of sweeping. Usually the health department is notified to coordinate the clean-up.

CRITICAL INTERVENTIONS

- Diagnosis of arsenic poisoning is based on appropriate symptoms and elevated urine arsenic level.
- Diagnosis of mercury poisoning depends on appropriate symptoms and elevated blood or urine mercury level.
- Supportive care is appropriate such as IV fluids.
- Obtain blood mercury or urine mercury or urine arsenic level.
- Administer BAL or DMSA chelation for severe symptoms.
- If radiopaque material is present in the GI tract after a recent ingestion, whole-bowel irrigation may be appropriate.
- Avoid medication that will prolong the QT interval in arsenic poisoning.

DISPOSITION

Patients with significant symptoms from arsenic or mercury poisoning should be admitted to the hospital. Patients with moderate toxicity should be observed for 6 to 8 hours in the ED prior to discharge, particularly with acute arsenic ingestion (ECG monitoring), elemental mercury inhalation and arsine gas inhalation. Most patients with mild to moderate toxicity can be treated as outpatients and should have a follow-up visit set up 2 to 3 days after the ED visit. A psychiatric evaluation prior to discharge is appropriate for patients with intentional exposures or ingestions.

Common Pitfalls

- Failure to identify exposure source and preventing future exposure.

- Inappropriate use of chelating agents in patients with mild toxicity who are asymptomatic.
- Failure to identify QT prolongation and arrhythmias in toxicity or delayed pulmonary edema in severe inorganic arsenic poisoning, or hemolysis and renal failure after arsine gas exposure.
- Failure to identify pulmonary effects from elemental mercury inhalation or severe neurologic and multisystem effects of organic mercury.

CHAPTER 327

Carbon Monoxide

Heather Long

Carbon monoxide (CO) is a colorless, odorless gas produced by the incomplete combustion of any carbon-containing material. CO is a leading cause of poisoning worldwide, with an estimated 50,000 emergency department (ED) visits annually in the United States for CO exposure (1). Common sources include fires (see Chapter 337), automobile exhaust and faulty home-heating systems (see Table 327.1). Non–fire-related CO poisoning peaks in winter months due to increased use of heating systems, alternative heat sources and practices such as warming up automobiles in attached garages. CO poisoning due to improper placement of generators and indoor use of charcoal grills and camp stoves often follows natural disasters. In the wake of Hurricane Sandy in 2012, more than 260 cases of CO poisoning were reported to poison centers (2). In 2007, CDC surveillance found there were 21,304 ED visits with confirmed cases and 439 deaths due to non–fire-related CO poisoning (3,4).

TABLE 327.1
Sources of Carbon Monoxide Poisoning

Fires/smoke inhalation
Automobile exhaust

Fuel-powered generators, space heaters, tools, etc.
Charcoal grills
Gas kitchen stoves
Camp stoves/lanterns
Boat motors
Propane-powered forklifts
Ice resurfacing machines
Wood pellet storage
Hookah pipes

CO causes tissue hypoxia, binding hemoglobin with an affinity approximately 250 times greater than that of oxygen. Thus, even at low CO levels, significant saturation of hemoglobin-binding sites with CO may decrease the oxygen-carrying capacity of the blood. In addition, CO binding to hemoglobin alters the shape of the oxygen–hemoglobin dissociation curve, effectively shifting it to the left, and further decreasing the intracellular oxygen concentrations. However, issue hypoxia from decreased oxygen delivery does not fully explain the observed toxicity from CO. Direct binding of CO to intracellular proteins appears to trigger an immune and inflammatory-mediated ischemic reperfusion injury to the brain characterized by generation of reactive oxygen species, lipid peroxidation, and apoptosis (1,5). Hypotension, thought due to myocardial depression as well as the vasodilatory effects of CO, appears to be a prerequisite for this ischemic reperfusion injury to the brain.

The toxic dose of CO depends on the rate of ventilation, the underlying health of the victim, and the presence of other toxins. Equilibrium is reached more rapidly in people who perform vigorous physical activity. As little as 0.1% CO (1,000 ppm) may produce potentially fatal 50% saturation of hemoglobin at equilibrium, although this might require several hours of exposure. The exposure limit in the workplace is 25 ppm as an 8-hour time-weighted average. The level considered immediately dangerous to

life or health is 1,200 ppm. People with underlying pulmonary or cardiovascular (CV) disease may not be able to tolerate hypoxia produced by even mild or moderate CO levels.

CO is rapidly absorbed from the lungs and carried in the blood as carboxyhemoglobin (COHgb). After removal from exposure, COHgb has an apparent half-life in room air of about 4 to 5 hours (6). Half-life drops to 1 to 2 hours at 100% oxygen at ambient pressure and to about 20 to 40 minutes with hyperbaric oxygen (HBO) at 2.5 atm. Methylene chloride is a paint stripper that can be inhaled ingested or absorbed through the skin. Because it is metabolized to CO by cytochrome P450 in the liver, the production of CO is ongoing which increases the apparent half-life of COHgb following methylene chloride exposure to at least 12 to 14 hours.

CLINICAL PRESENTATION

The signs and symptoms of CO poisoning are highly variable and non-specific but primarily involve the brain and the heart, the organs most sensitive to CO poisoning. Headache is the most common complaint followed by dizziness, nausea, vomiting, and fatigue. With more significant CO exposures, confusion, syncope, shortness of breath, tachycardia, tachypnea, and chest pain may occur. Severe poisoning may cause coma, seizures, hypotension, cardiac dysrhythmias, and death. Patients may present with focal neural deficits resembling stroke. Sensorineuronal hearing loss and cortical blindness are reported.

Although the severity of intoxication usually parallels the COHgb concentration, there are reports of patients with severe intoxication with prolonged exposure at relatively low levels and of patients with high levels after a short exposure but minimal symptoms.

In a large case series, myocardial injury developed in 20% of 250 CO-poisoned patients. Predictors of myocardial injury are male sex, an initial GCS <14 and CO exposure ≤ 2 hours (3). Myocardial manifestations include ischemia, ST and non-ST elevation myocardial infarction, thromboembolic events, and dysrhythmias

including atrial fibrillation, ventricular fibrillation, Brugada pattern changes and QT prolongation.

Other acute manifestations of CO poisoning include acute kidney injury and retinal hemorrhage. A cherry-red coloration of the skin, mucous membranes, and venous blood on rare occasion may occur from the bright red color of the COHgb complex. However, its presence or absence cannot be considered diagnostic; it is more likely to be noted at autopsy than in patients who survive. Arterial blood gas analysis and serum electrolytes often reveal metabolic acidosis caused by tissue hypoxia–ischemia. The arterial PaO_2 and the calculated oxygen saturation are usually normal because dissolved oxygen in the serum is not affected by CO. The oxygen saturation measured directly by co-oximetry is less than that calculated from the PO_2 by an amount roughly equal to the percent COHgb, but typically the oxygen saturation measured by pulse oximetry is falsely normal (7).

A myriad of persistent or delayed neurologic and neuropsychiatric sequelae may develop following CO poisoning. Deficits range from subtle alterations in personality, memory deficits, headaches and difficulty concentrating to blindness, deafness, parkinsonian features, dementia, and permanent vegetative state. Deficits may be permanent or improve with time. Delayed neurologic sequelae are associated with neurologic symptoms including syncope and coma at time of presentation, but mild CO poisoning does not exclude its development.

DIFFERENTIAL DIAGNOSIS

Influenza-like illness is the most common misdiagnosis and not surprising given the overlap in symptoms, peak incidence in winter months and the ability to affect multiple household members simultaneously. Other causes of coma and altered mental status should be sought, such as hypoglycemia, head trauma, stroke, meningitis, and drug or alcohol intoxication. Almost half the patients with intentional CO poisoning ingest other potential toxins including alcohol (8). In addition to CO poisoning, other toxic gases

should be considered in any patient with smoke inhalation. Cyanide, hydrogen sulfide, agents that cause methemoglobinemia, and other toxins may produce symptoms and signs of systemic hypoxia that are similar to those of CO (6).

ED EVALUATION

A high index of suspicion is key to the diagnosis of CO poisoning. Think CO in all patients who present with headache and especially in those who present with confusion or altered mental status and who are by default, poor historians. Think CO in winter and following large power outages. High-risk history includes smoke inhalation, household members with similar symptoms, found in car with engine running or adjacent house, use of fuel-powered tools, generators, pool, and space heaters, etc. especially in poorly ventilated areas and riding in motor boats, houseboats, and beds of pick-up trucks.

Immediate evaluation in the ED should include rapid neurologic assessment and determination of the COHgb level. COHgb is measured in the laboratory by a co-oximeter and may be performed on either a venous or arterial blood gas sample. Normal COHgb levels range from 3% to 5% in nonsmokers and up to 10% in smokers. Fingertip pulse co-oximeters are devices that measure COHgb noninvasively. Agreement between pulse co-oximeters and laboratory-measured COHgb levels is variable, and CO may be undetectable by pulse co-oximetry in the setting of hypoxemia (9). Pulse co-oximetry may be useful as a rapid screening test in the field or in the ED but cannot be used as a substitute for laboratory-measured COHgb in guiding the management decisions of an individual patient.

Depending on severity, further diagnostic tests may be indicated including blood gas analysis, lactate concentration, metabolic profile, creatine phosphokinase, troponin, ECG, and chest radiography. An elevated lactate level in the context of smoke inhalation can suggest concomitant cyanide poisoning. Check fingerstick glucose in all patients who present with altered mental

status. Unsuspected acetaminophen may be detected by measuring a serum level in cases of intentional CO poisoning; additional serum and urine ethanol and drug testing should be used as suspected. Potential injuries sustained in the setting of trauma should guide ordering of additional studies.

Lesions in the basal ganglia, the area of the brain most susceptible to CO, may be evident on CT scan within 12 hours of significant CO exposure. MRI is better than CT at detecting these lesions and diffusion tensor imaging in particular, may be useful in predicting severity and outcome (6).

KEY TESTING

- COHgb level from venous or arterial blood sample
- Evaluate for anion gap metabolic acidosis in severely poisoned patients
- Send lactate in severely poisoned patients

ED MANAGEMENT

Oxygen is first-line treatment for anyone with suspicion of CO exposure until confirmatory COHgb level is attained and should be provided through a nonrebreather mask with an oxygen reservoir bag or an endotracheal tube. Oxygen should be administered to waiting room patients prior to further triage and registration and continued until symptoms are resolved and COHgb is less than 5%. Advanced life-support measures and cervical spine precautions should be instituted as needed. The only decontamination needed is removing the victim from the toxic environment with the exception of exposure to the paint stripper methylene chloride. Treat hypotension with IV crystalloid and vasopressors and potential myocardial ischemia with cardiac monitoring, serial ECGs and treatment per standard chest pain protocols. Consider hydroxocobalamin for critically ill smoke inhalation victims with CN poisoning (see Chapter 313). Because acidosis may facilitate oxygen delivery to the tissues by moving the oxygen–hemoglobin dissociation curve to the right, mild-to-moderate metabolic acidosis

(i.e., serum pH 7.2 to 7.3) should not be treated with sodium bicarbonate.

HBO, 100% oxygen provided under pressures >1 atm, should be considered in all cases of significant CO poisoning. It reduces the half-life of COHgb to about 20 minutes, but more importantly, may prevent CO-induced postischemic reperfusion injury and reduce the risk of persistent/delayed neurologic and neuropsychiatric sequelae. Animal studies show a mechanism of action and convincing data that HBO modulates CO-induced vascular injury and improves CV status and neurologic outcome (1,5). Clinical studies, most with marked methodologic flaws, have found mixed results. The one large, prospective, double-blind randomized controlled trial found treatment with HBO conferred a small but statistically significant benefit in neurologic outcome (7).

Controversy remains about which patients should receive HBO treatment. Most hospitals do not have ready access to a hyperbaric chamber so treatment requires a transfer and all the inherent risks of transporting patients. Ideally, only those patients thought to be at greatest risk for persistent/delayed neurologic sequelae would be referred for potential HBO, but those criteria have not been prospectively validated. See Table 327.2 for suggested indications for HBO. COHgb levels do not predict clinical outcome, but most experts recommend HBO for patients with high levels, generally ≤25%. Aside from the risks, cost and inconvenience of transport, the most common side effect of HBO is barotrauma to the middle ear which can be prevented by myringotomy.

TABLE 327.2
Indications for Potential Hyperbaric Oxygen Therapy

Syncope
Prolonged exposure (>24 hrs)
Age ≥36 yrs
Abnormal cerebellar function
Seizure
Coma
Altered mental status
COHgb level >25%

Pregnant women and children pose a special problem in CO poisoning. The maternal COHgb level does not predict fetal outcome, but the maternal clinical presentation does. Severe CO poisoning in the mother is associated with CNS damage and fetal demise while pregnant women with mild poisoning have good outcomes (10). Fetal hemoglobin may not have a greater affinity for CO as was previously thought, but CO does take longer to be eliminated in the fetus. COHgb levels may be difficult to interpret in infants as CO levels are naturally higher in infants than in older children and adults and may be even higher in the setting of jaundice. In addition, the co-oximeter may give a falsely elevated COHgb in the presence of fetal hemoglobin. Children are thought to be at increased risk of CO poisoning because of their higher metabolic rate and to become symptomatic at lower COHgb levels than adults. Prolonged oxygen therapy and a lower threshold for HBO are often recommended for pregnant women and children, although, once again, studies are lacking.

The prognosis after severe CO poisoning is unpredictable but grim. While survival of awake patients is high, as many as 40% of victims have permanent neurologic injury. Patients with an abnormal computed tomography, single-photon emission computed tomography scan, or magnetic resonance imaging scan on admission appear to be at higher risk for permanent sequelae (6).

CRITICAL INTERVENTIONS

- Administer oxygen at 10 to 15 L/min by nonrebreather mask with an oxygen reservoir bag or 100% by endotracheal tube to

all patients with possible CO poisoning.
- Consider HBO therapy for patients with a history of loss of consciousness or syncope, cerebellar findings, seizure, coma, prolonged exposure times, COHgb levels 25% or higher, age over 36 and for pregnant women and children.

DISPOSITION

Patients with mild CO poisoning should be treated with 100% oxygen until symptoms resolve and COHgb is less than 5%. Patients with loss of consciousness, seizures, or evidence of MI or ischemia should be admitted to the hospital; severely poisoned patients will require intensive care admission. Many authorities would also admit any patient with a CO-hemoglobin level >25%, regardless of symptoms.

HBO treatment may be indicated for some patients (Table 327.2) and a poison center or medical toxicologist may be able to assist. A critical care nurse or paramedic should accompany the potentially unstable patient during transport to an HBO facility. Once the acute episode of poisoning has resolved, patients should be referred for follow-up neuropsychiatric evaluation. Those discharged from the ED should be instructed to return to the ED if any neurologic symptoms develop.

Patients who are discharged after unintentional poisoning should have a safe environment to avoid repeat exposure. This may require the fire department to measure ambient levels or a stay in a temporary shelter until a home or other setting can be cleared of CO.

Common Pitfalls

- Failure to consider the diagnosis of CO poisoning in patients presenting with headache, altered mental status, and influenza-like illness, particularly in cold climates or seasons.
- Failure to consider the ingestion of alcohol or other drugs in patients with suicidal exposure to CO.

- Failure to appreciate that the arterial blood gas PaO_2, calculated oxygen saturation, and pulse oximetry oxygen saturation are usually normal despite severe CO poisoning.
- Failure to appreciate that the severity of poisoning depends on the duration of exposure and that carboxyhemoglobin levels may not correlate with the severity of poisoning.
- Failure to warn patients about the possibility of delayed neurologic toxicity and to return if symptoms develop.

CHAPTER 328

Corrosives and Chemical Burns

Larissa I. Velez

Most corrosive injuries involve acids or alkalis. Other corrosives damage tissues by various mechanisms, including oxidation, reduction, vesication, desiccation, metabolic inhibition, or cellular poisoning. Fluoride and hydrofluoric acid are discussed in Chapter 330, and chemical warfare agents (including the blistering agents) are discussed in Chapter 350. This chapter focuses on the damaging effects of acids and alkali.

Acids (pH <7) are proton donors that dissociate into conjugate bases and free hydrogen ions (H^+) in solution. Alkalis (pH >7) accept protons, resulting in the formation of conjugate acids and free hydroxide ions (OH^-). In general, substances with a pH <3 or >11 have the most potential to cause significant corrosive injury, as they produce more free ions (Table 328.1). Acids denature proteins and cause coagulation necrosis. The formation of a firm coagulum or eschar often limits the penetration of injury. Alkalis cause liquefaction necrosis, which dissolves proteins and saponifies fats. The injured tissues slough, allowing for deeper injury when compared to acids.

TABLE 328.1
Approximate pH of Some Common Solutions

Solution	pH
1.0 M HCl	0
Battery acid (1% solution)	1.4
Acid toilet cleaner (1%)	2.0
Citrus juices	1.8–4
Wines	2.8–3.8
Black coffee	5.0
Rainwater	6.5
Water (25°C)	7.0
Bleach (1% solution)	9.5–10.2
Automatic dishwasher detergents	10.4–13
Laundry detergents	11.6–12.6
Ammonia cleaners (<10%)	11.9–12.4
Alkaline drain cleaners	13.3–14
1.0 M NaOH	14
Saturated ammonia solution	15

The extent, location, and severity of gastrointestinal (GI) injury depend on the physical state of the corrosive or chemical agent, the pH and concentration of the agent, the amount ingested, the duration of tissue contact, the presence of food in the stomach, and the tonicity of the pyloric sphincter. Solid particles dissolve on contact with body fluids, producing highly concentrated solutions, which may result in severe localized damage. Solids and viscous solutions tend to adhere to tissues and frequently result in proximal rather than distal involvement. Larger amounts, which are common with intentional ingestions, have a higher potential for severe injury. However, acids usually have a strong odor and result in immediate pain and smooth muscle spasm, which may limit the amount ingested. Alkalis are often odorless and do not cause immediate pain after contact. In addition, sloughing of tissue after liquefactive necrosis results in deeper penetration of alkalis. Because of these characteristics, alkali ingestions usually involve larger volumes and result in more severe injury. In general, longer contact times with a corrosive substance results in greater injury. Finally, the presence of food in the stomach is somewhat protective. Systemic toxicity sometimes accompanies severe GI injuries and is

usually secondary to tissue inflammation, necrosis, perforation, acidosis, and infection. Fluid and electrolyte shifts can accompany extensive burns and result in hypovolemic shock. Some corrosives also cause systemic toxicity when absorbed.

The subsequent injury and repair processes are similar for both acids and alkali. There is bacterial invasion after 24 to 48 hours, an inflammatory response, and development of granulation tissue. Because collagen deposition may not begin until the second week, tensile strength of the healing tissue is low during the first 3 weeks (1). Scar retraction begins in the third week, commonly continuing for months, and may result in stricture formation. Finally, mucosal repair can take weeks to months.

Ocular damage is most severe following alkali burns as a result of early disruption of the corneal epithelium and rapid tissue penetration. As with ingestions, the overall severity of alkali burns is generally more than that seen with acids.

Chemical burns caused by corrosives differ in several important ways from thermal burns. First, the initial severity of the injury may be underestimated because tissue penetration of the chemical may be deeper than anticipated by visual inspection. In addition, tissue penetration and damage may continue for hours to days. Furthermore, absorption of the chemical may result in systemic toxicity. As with ingestions, the severity of the dermal injury is dependent on several factors, including the specific mechanism of toxicity and concentration of the agent, duration of exposure, surface area exposed, thickness of the skin involved, and depth of penetration. Patient factors such as age, pre-existing conditions of the skin, and concurrent illnesses also affect the severity of the injury.

CLINICAL PRESENTATION

Sites commonly affected by corrosive ingestion are the oropharynx, esophagus, and stomach, although injury may occur as far as the proximal jejunum (2,3). Injury to other organs, including the heart, liver, and pancreas, has been reported, but is rare (4,5).

Patients usually present with oral, throat, chest, or abdominal pain. Dysphagia, drooling, and vomiting are common. Children may refuse to drink, cry excessively, or be unable to swallow their secretions. Stridor, hoarseness, hematemesis, and melena occur less frequently (6). Tachypnea can occur from aspiration of the corrosive with resultant pneumonitis or as a compensation for a metabolic acidosis. The metabolic acidosis may reflect tissue necrosis or the systemic absorption of ingested acids.

On inspection, superficial burns of the oropharynx are often covered with a pale membrane, and deeper burns are black, hemorrhagic, or friable but the presence or absence of burns in the oropharynx does not reliably predict more distal injuries (3,6). Full-thickness injuries to the esophagus or stomach are at risk of perforation and fistula formation into the trachea, mediastinum, or peritoneum (3). Mediastinitis can present with chest pain, respiratory distress, fever, subcutaneous emphysema, pleural rub, and Hamman sign (an audible crunch with each heart beat). Chest radiographic findings of mediastinitis may include mediastinal widening, pleural effusion (usually left-sided), pneumomediastinum, and pneumothorax.

The abdominal examination is an unreliable indicator of the severity of the injury, but frank peritonitis is an ominous sign. Peritonitis may result from viscous perforation or the extension of severe gastric burns to surrounding abdominal organs. Patients with peritonitis may have marked third-spacing of fluids, resulting in abdominal distention and hypotension. Abdominal compartment syndrome, or intra-abdominal hypertension, has been reported.

The late presentations after a corrosive ingestion include dysphagia, nausea, and vomiting as a result of the formation of strictures. Esophageal strictures develop in up to 70% of patients with deep esophageal ulcers and in nearly all patients with areas of necrosis (3). Ulceration superficial to the muscularis mucosa layer does not lead to stricture formation. Half of all esophageal strictures develop during the initial hospitalization, and 80% are evident within 2 months. Esophageal carcinoma, a late sequela of alkali

ingestion, has been diagnosed after a latency period of about 40 years (1) but is only rarely reported with acid burns.

Ocular injury most commonly results from splash exposures at home or in the work environment. Injuries have also been reported after airbag deployment, where sodium hydroxide is produced (7,8). The severity of these injuries ranges from transient irritation to severe disabling ocular damage and blindness. Manifestations include immediate eye pain, photophobia, blepharospasm, lacrimation, conjunctival injection or hemorrhage, and decreased visual acuity. The pupils may be nonreactive as a result of severe iritis. Intraocular pressure rises with damage to the trabecular meshwork, resulting in new glaucoma. With more significant involvement, chemosis and corneal edema, opacification, sloughing, ulceration, and necrosis occur. Destruction of blood vessels may result in a very white sclera indicative of corneal ischemia which along with corneal opacification are both ominous signs. If penetration is deep enough, retinal damage occurs. Ultimately, inflammation leads to fibrosis, synechiae, and cataract formation.

Dermal exposure usually results in immediate pain at the affected site, but the onset of pain can sometimes be delayed for several hours, especially with hydrofluoric acid (see Chapter 330). Petroleum distillates, weak sodium hydroxide solutions, and wet cement, which is an alkali, typically do not produce burns unless allowed to remain in contact with the skin for prolonged periods. Such exposures may initially appear trivial but can progress to full-thickness burns. Chemical burns rarely blister, and the affected skin is usually dark, insensate, and firmly attached regardless of the burn depth. With time, the skin hardens and cracks, exposing the underlying dermis or subcutaneous tissue. Healing of chemical burns usually takes longer than for thermal burns.

DIFFERENTIAL DIAGNOSIS

With ingestions, it is important to determine the coingestion of other agents. If shock or altered mental status is present soon after ingestion, other causes than caustics should be sought. The ingestion

of heavy metals and hydrocarbons can cause symptoms similar to a caustic ingestion. Allergic reactions may also present with some of the features of corrosive ingestion, specifically if the hypopharynx or larynx is involved. Infections such as epiglottitis, croup, retropharyngeal abscess, and mucosal ulceration as a result of herpesvirus or coxsackievirus should be considered in children.

The differential diagnosis of corrosive injury to the eye includes traumatic corneal abrasion or ulceration, corneal foreign bodies, allergic reactions, infectious processes such as viral or bacterial conjunctivitis, iritis, iridocyclitis, acute narrow-angle glaucoma, and exposure to fumes, vapors, and other sensitizing agents.

Considerations in the differential diagnosis of chemical dermal injuries include thermal burns, radiation burns (including sunburns and from welding), mechanical irritation or trauma, allergic reactions and drug eruptions (such as Stevens–Johnson syndrome or toxic epidermal necrolysis), contact dermatitis, infections, and bacterial toxin-mediated conditions such as staphylococcal scalded skin syndrome or toxic shock syndrome.

ED EVALUATION

The identity, concentration, and amount of chemical or product involved and the time and circumstances of exposure should be determined as soon as feasible. Product labels, when available, should be examined for ingredients and signal words. The signal words “caution,” “warning,” and “danger” identify a product as a weak irritant (to eyes, nose, and throat), strong irritant (to skin and mucous membranes), or corrosive (capable of causing permanent or fatal tissue damage), respectively. If a sample is available, measure its pH. A pH meter is more accurate than pH paper (e.g., pHydrion paper, which is also used for testing amniotic fluid) but is not generally available. A regional poison-control center can assist with identifying the product and for advice on evaluation and management of the exposure. However, none of these should delay the patient evaluation and management.

In patients with corrosive ingestion, attention should initially be directed to airway patency, because obstruction may develop with progressive mucosal edema. In the absence of stridor or respiratory distress indicating the need for immediate endotracheal intubation, patients with a hoarse voice or respiratory symptoms should have the upper airway assessed by direct fiberoptic laryngoscopy. Patients suspected of having a significant corrosive injury should also have an electrocardiogram, blood-gas analysis, complete blood count, type and crossmatch, prothrombin time, electrolyte, glucose, liver-function, and renal-function tests. Radiologic studies should include an upright chest radiograph if the patient has respiratory symptoms and abdominal films if perforation is suspected.

Endoscopy of the upper GI tract is the gold standard for the diagnosis of corrosive injury (9). Endoscopy should be performed in all symptomatic patients. A complete lack of symptoms or signs suggests that significant injuries are absent and that endoscopy is not necessary (6). Nevertheless, endoscopy should be considered for asymptomatic patients who have intentionally ingested a strong acid or alkali or if the history is unreliable. Endoscopy is optimally performed 12 to 24 hours after exposure (3). If undertaken earlier, the full extent of injury may not be apparent; if performed later, the risk of perforation may be increased (2).

Esophageal and gastric burns are graded in a similar fashion as dermal burns. Grade 1 burns just have erythema of the mucosa (3). Grade 2 burns have partial-thickness submucosal lesions, ulceration, and exudates. Some authors consider 2 a burns as noncircumferential, and 2b as near circumferential. Grade 3 burns are deep, full-thickness burns with ulcers and necrosis into the periesophageal tissues (6). Third-degree burns have an 85% incidence of stricture development. Overall, the best predictor for the development of strictures is the severity of the initial injury. Endoscopic ultrasound has been used to measure injury to the muscularis layer. Injury to the muscularis layer has also been shown to correlate with late stricture formation (10). Contrast esophagography is less sensitive than endoscopy in assessing burn injury, although it is useful for detecting perforation. A water-

soluble contrast agent (gastrografin) must be used whenever perforation is suspected. Cine-esophagogram can detect esophageal motility disorders and gastroesophageal reflux, which also predict stricture formation. CT scan has also been used for detection of stomach perforation. A grading scale for caustic burns on CT scan can be used (10).

With symptomatic ocular exposures, decontamination must always precede the formal evaluation of the eye. A complete eye examination including measurement of visual acuity, conjunctival pH, and a slit-lamp examination should follow the decontamination. If injury to the anterior chamber is suspected, the intraocular pressure should be measured. However, this last step must be avoided if there is a concern for ocular globe disruption.

The assessment of dermal injuries is similar to that for thermal burns. Location, size, color, texture, and neurovascular status should be noted. If the affected area is >5% of total body surface area or if systemic toxicity is possible, a more thorough physical examination and laboratory testing can be performed to assess for systemic involvement.

KEY TESTING

- Early endoscopy for all symptomatic caustic ingestions, regardless of oral findings
- Direct fiberoptic laryngoscopy for hoarseness, stridor, or respiratory symptoms
- Chest and abdominal radiographs, and esophagogram with low–molecular-weight contrast, for possible esophageal or gastric perforation
- Laboratories for supportive care include CBC, chemistries, and coagulation studies
- Conjunctival pH testing after eye irrigation

ED MANAGEMENT

Any patient with evidence of significant upper airway obstruction such as severe respiratory distress, stridor, or inability to speak

should undergo immediate endotracheal intubation. Delay in securing a definitive airway will only result in further development of airway edema and increase the difficulty with endotracheal intubation. This, however, is a rare event (10).

The efficacy of GI decontamination is limited. However, the mouth should be rinsed liberally with water in patients with oral burns. Because emesis re-exposes the esophagus to the corrosive agent and increases the risk of aspiration, antiemetics should be given to patients with persistent nausea or vomiting. A nasogastric tube for stomach emptying may be considered in recent, large-volume ingestions. Activated charcoal should be avoided since it obscures the endoscopist's view, and most corrosives are not significantly adsorbed by charcoal. Dilution of gastric contents with oral fluids within minutes of ingestion may be beneficial, although the current evidence is inconclusive (10). If dilution is to be used, it should be within minutes of exposure in patients with a normal airway and mental status, without significant nausea, vomiting, or pain, and who are able to speak and cooperate. The amount swallowed should be limited to 5 mL/kg to avoid inducing emesis.

Although corticosteroids reduce the incidence and severity of esophageal strictures in animal studies, their value in humans is controversial. In human trials in which steroids were not given until up to 24 hours after exposure, there are conflicting conclusions as well as points of general agreement. Patients with first-degree esophageal burns do not require steroids, because strictures do not develop in this group. Steroids do not appear to alter the development of esophageal strictures in patients with extensive areas of deep ulceration or necrosis (grade 3 burns) and may actually increase the rate of complications such as infection, hemorrhage, or perforation. For patients between these two extremes, whose injuries consist of circumferential or extensive superficial ulceration or small areas of deep ulceration or necrosis, steroids are of potential benefit. The most recent pooled analysis of the available data did not show a statistically significant benefit of steroids for second-degree burns (11). An earlier systematic review of published cases also failed to show benefit in second-degree burns

(12). The decision to use steroids is based on the grading of the burns, which highlights the importance of early endoscopic evaluation.

Concomitant penicillin, ampicillin, or clindamycin are recommended whenever steroids are being used. Although they are of no proven benefit in promoting healing or reducing complications, antacids, sucralfate, H_2 blockers, proton pump inhibitors, and analgesics (ibuprofen) can provide symptomatic relief (2,10). Oral medications and feedings should be withheld until after endoscopy, and then should be given only to patients with injuries limited to mucosal inflammation or small areas of superficial ulceration. These patients may be given oral fluids when they are able to swallow their own secretions. Those patients with more severe injuries should receive intravenous fluids and nothing by mouth.

Surgical exploration is indicated if perforation is confirmed by radiographs or endoscopy, when there is persistent hypotension, or in the presence of abdominal rigidity. Surgical exploration has also been recommended in patients who are at high risk of perforation, sepsis, necrosis, or hemorrhage. Because endoscopy cannot fully evaluate the depth of the burns (e.g., the status of the serosal surface), exploration has also been proposed for patients with grade 2 or 3 burns to overcome this limitation. In one study, a serum pH <7.22 and a base excess more than –12.0 were predictors of severe injury requiring an emergency salvage operation (10).

Immediate copious irrigation is the single most important intervention in the management of eye exposures (13). The severity of ocular damage at the time of presentation is a good predictor of the ultimate outcome, as are timeliness and adequacy of irrigation. Ideally, irrigation will have been performed immediately at the time of exposure in the home or workplace and continued en route to the hospital. The patient can use a running faucet or hold his or her breath while blinking while *the face is in a pan of water*. If the patient has significant pain, irrigation must again be performed in the emergency department (ED). Acceptable irrigation solutions

include tap water, normal saline, Ringer lactate, or D_5W. Commercially available irrigation solutions (Previn, Diphoterine) are also acceptable, but the irrigation should not be delayed while these solutions are obtained irrigation will be aided greatly with topical anesthetic solution, eyelid retractors, intravenous analgesics, or sedatives. The eyelids should be everted, and any particulate matter should be removed with a cotton swab. Continuous irrigation of the eye is made easier with use of a scleral lens with inflow channel (Morgan Therapeutic Lens), or one can simply irrigate manually with intravenous tubing connected to irrigation solution. Initially the eye should be irrigated with 1 L and for at least 20 minutes. For highly corrosive substances, especially alkali exposures, irrigation should continue for at least an hour.

After irrigation, the pH of the inferior cul-de-sac should be tested with litmus or pH paper. If a neutral pH of 7 to 8 has not yet been achieved, continued irrigation is warranted. Once a neutral conjunctival pH is achieved, the pH should be rechecked every 30 minutes for 2 hours, because corrosive material may be slowly released from corneal tissue for several hours. A subsequent change in pH indicates the need for further irrigation.

Standard treatment for corneal injuries includes topical antibiotics, steroids, cycloplegics, and mydriatics. If intraocular pressure is elevated, topical timolol maleate and oral acetazolamide may be required. Tetanus prophylaxis and analgesics should be administered if needed.

Initial management of dermal injuries is also directed at rapid decontamination with copious water irrigation of the skin surface with water for most exposures. Ideally, irrigation will have been initiated immediately at the scene and continued en route to the hospital (14). Delayed decontamination can result in increased tissue damage and deeper penetration of the offending agent. In industrial accidents, rescuers should wear appropriate protective gear such as gloves, gowns, masks, and eye shields. All contaminated clothing, footwear, jewelry, and contact lenses should be removed from the victim. Immediate irrigation with water should

never be delayed to search for an alternative irrigation solution. Irrigation should continue for at least 20 minutes. A longer period of irrigation lasting up to several hours is required for alkalis and other serious exposures. Gently brush away particulate material before irrigation is started. Adherent materials may be removed by gentle scrubbing with soapy water while avoiding abrasions. Appropriate analgesia and tetanus prophylaxis should be provided, and wounds should be treated with topical antibiotic cream and protective dressings.

Irrigation should not be performed for burns caused by elemental forms of alkali metals such as sodium, potassium, lithium, cesium, and rubidium. These elements react with water to form hydroxides, strong bases that will significantly increase tissue damage. Furthermore, ignition or explosion occurs when water contacts pure magnesium, sulfur, strontium, titanium, uranium, yttrium, zinc, and zirconium. These two groups of substances should be covered with mineral oil to isolate them from water. Any solid particles that are removed from the victim must be stored in mineral oil to prevent further reactivity. These specific caustic agents are not commonly available and are thus seldom encountered. Patients with such exposures may come to the ED with Material Safety Data Sheets (MSDS) from their workplace. These data sheets can provide specific information about the agent.

CRITICAL INTERVENTIONS

- Evaluate the airway in patients with ingestions or facial-skin exposures, and intubate patients with respiratory distress, stridor, or inability to speak.
- Begin irrigation immediately, and continue for at least 20 minutes in symptomatic patients with eye and skin exposures.
- Consult a gastroenterologist for the endoscopy of patients with GI symptoms or suicidal corrosive ingestion.
- Consult a surgeon for patients with evidence of perforation, endoscopic evidence of severe GI injury, peritoneal signs, hypotension, or metabolic acidosis after corrosive ingestion.

- Consult an ophthalmologist for patients who have evidence of corneal injury or persistent pain after eye exposure.
- Consult a regional burn center for patients with significant dermal injury.

DISPOSITION

Exposed patients who are asymptomatic or become asymptomatic after oral rinsing and dilution may be discharged from the ED after an observation period (1). It is generally agreed that patients who are asymptomatic after unintentional ingestions will have normal endoscopies (6). For patients with more significant exposures, endoscopy should be arranged, with transfer to an appropriate facility if necessary. Suspected suicidal ingestions should have a psychiatric evaluation and the possibility of nonaccidental injury should be considered in all pediatric cases (1). Patients with no visible injury on endoscopy and those with injuries limited to mucosal inflammation or small areas of superficial ulceration may be medically discharged as long as they are able to tolerate oral fluids (15). Patients with persistent symptoms or inconclusive findings at endoscopy should be admitted for observation. If symptoms persist, endoscopy should be repeated.

Patients with mild chemical conjunctivitis can be referred to an ophthalmologist for follow-up the next day. Immediate ophthalmology consultation should be obtained for those with evidence of corneal injury or persistent pain. Patients with significant eye injuries should be admitted to the hospital for further irrigation, for assessment of injury progression and the need for surgical intervention, and to ensure initial compliance with the medical regimen.

Consultation with a general surgeon, plastic surgeon, or regional burn center is recommended for patients with significant dermal injuries. Patients with minor injuries may be discharged, if the patient is reliable and follow-up the next day can be arranged. Patients with systemic toxicity; second- or third-degree burns; extensive first-degree burns (>5% of body surface area); burns to

the face, eyes, ears, perineum, hands and feet; and high-risk patients such as those with significant pre-existing illness, the elderly, and psychiatric or otherwise noncompliant patients should be admitted (16).

Common Pitfalls

- Inducing vomiting by giving excessive amounts of oral fluid for dilution.
- Giving activated charcoal, which is not indicated for acid or alkali ingestion, and which will obscure endoscopic evaluation.
- Assuming that the absence of oropharyngeal burns precludes the presence of significant GI injury in symptomatic patients.
- Failing to continue eye irrigation long enough, as determined by conjunctival pH testing.
- Underestimating the severity of dermal exposures and failing to provide adequate decontamination.

ACKNOWLEDGMENT

CHAPTER 329
Cyanide

Heather Long

Acute cyanide (CN) poisoning is a rare and potentially fatal but treatable condition. Potential sources of CN include smoke inhalation, ingestion of CN salts and cyanogenic compounds, occupational exposures, and iatrogenic exposures (see Table 329.1). Hydrogen cyanide (HCN) gas for chemical warfare dates to the time of Napoleon III and was used again during World Wars I and II and in concentration camps during World War II. Both HCN and CN salts remain chemical terrorism threats. Most CN deaths arise from intentional suicides, particularly among those with occupational access, for example, chemists, jewelers (1). A recent case series describes intentional self-poisoning and suicide with cyanide-containing jewelry and metal cleaners purchased at Southeast Asian ethnic markets among the US Hmong communities (2). The contribution of HCN to smoke-inhalation injury among fire victims is increasingly recognized (see Chapter 337).

TABLE 329.1
Sources of Cyanide

Fires and smoke inhalation: Combustion of wool, silk, rubber, polyurethane, and nitrocellulose releases CN

Occupational exposures: Industrial processes that require CN reagents include electroplating, metal refining, fumigation, and photography

Cyanogenic compounds: Acetonitrile (found in artificial-nail remover); CN is released after ingestion and metabolism by the cytochrome P-450 system

Cyanogenic foods: Pits of the *Prunus* species (apricot, bitter almond, cherry, peach) contain the cyanogen amygdalin. Cassava (tuber consumed in many developing countries) contains two cyanogenic compounds

Iatrogenic: Sodium nitroprusside contains five molecules of CN. If given at high dose or for long duration, it may overwhelm body's stores of thiosulfate and cause CN poisoning

CN toxicity depends on the dose, the route of exposure, and the form of CN. CN toxicity may occur following inhalation, ingestion, and parenteral or dermal exposure, with inhalation and ingestion accounting for most significant toxicity reported. Inorganic CN exists either as a gas or a salt. HCN is a gas at standard temperature and pressure. HCN may be immediately lethal at an air concentration of 270 ppm, and exposures to >110 ppm for >30 minutes are potentially lethal. CN salts such as potassium cyanide (KCN) generate HCN on exposure to acid. The HCN may then be inhaled or, if the salt is ingested, absorbed into the bloodstream. The lethal oral dose of KCN is 200 mg, with death in approximately 20 minutes. Toxicity following ingestion of cyanogenic compounds, for example, acetonitrile, may be delayed several hours while the parent compound is metabolized to yield CN.

At the cellular level, CN produces hypoxia by complexing with the ferric iron of mitochondrial cytochrome oxidase a_3 of the electron-transport chain, blocking oxidative phosphorylation and formation of adenosine triphosphate (ATP). Anaerobic metabolism prevails, and lactic acid accumulates. Central nervous system (CNS) toxicity arises from the decrease in oxygen utilization as well as oxidant-stress–induced lipid peroxidation and the cell death triggered by increased release of excitatory neurotransmitters (3,4).

CLINICAL PRESENTATION

Inhalation of high concentrations of HCN may cause sudden loss of consciousness after only a few breaths. With ingestion of alkaline CN salts (calcium CN, KCN, sodium CN), life-threatening symptoms may occur in 15 minutes to 1 hour. In fatal cases, rapid progression to coma, seizures, dysrhythmias, intractable hypotension, apnea, and death is common.

Onset of symptoms may be delayed after exposure to cyanogens such as laetrile and cyanogenic glycosides from plant sources (up to 1.5 hours) or aliphatic nitrile compounds such as acetonitrile in artificial glue-on-nail removers (up to 6 to 12 hours) (5,6). Systemic poisoning may occur after dermal HCN exposure.

Tissues with the greatest oxygen demand (myocardium and brain) are most profoundly and rapidly affected by CN. Initial CNS and cardiovascular (CV) stimulation is followed by depression. Initial signs and symptoms of CNS stimulation include giddiness, headache, and anxiety followed by confusion, seizure, and coma. The initial CV response may be characterized by a brief period of hypertension and bradycardia followed by hypotension and a reflex tachycardia. Ultimately there is hypotension and bradycardia and cardiac arrest.

Early in the clinical presentation, there may be CNS-mediated hyperpnea that is later followed by bradypnea. Both cardiogenic and noncardiogenic pulmonary edema (more correctly termed *acute lung injury*) are reported at autopsy. Gastrointestinal symptoms including nausea, vomiting, and abdominal pain may follow ingestion of CN salts and cyanogenic compounds.

Classically, CN poisoning is associated with a cherry-red skin color resulting from the inability of tissues to extract oxygen from the blood and the resulting increased oxygen saturation of venous hemoglobin. CN itself does not cause cyanosis; however, patients with apnea and circulatory collapse may exhibit cyanosis. The smell of bitter almonds with CN poisoning is sporadically present, and even when present, only 60% of people are able to detect it.

Sodium nitroprusside treatment may cause iatrogenic CN poisoning within hours to days, typically in patients with renal failure. Manifestations include altered mental status and metabolic acidosis, particularly in the setting of tachyphylaxis to nitroprusside

therapy. CN poisoning in this setting can be prevented by the concomitant administration of hydroxocobalamin or sodium thiosulfate.

DIFFERENTIAL DIAGNOSIS

Early symptoms may be confused with anxiety or hyperventilation, which are common after nontoxic exposures. Rapid development of more serious clinical signs differentiates these benign conditions and nontoxic CN exposures from significant CN poisoning. Hydrogen sulfide and sodium azide poisoning may cause similar findings, and diabetic decompensation has been initially suspected in patients who were later found to have ingested CN.

The following laboratory values may suggest the diagnosis when no history is available: Plasma lactate level >8 mmol/L and elevated anion gap metabolic acidosis. Decreased tissue oxygen extraction from the blood results in a relatively normal pO_2 in ventilating patients and an elevated peripheral venous pO_2 (>40 mm Hg) or decreased arteriovenous O_2 saturation difference (central venous or mixed pulmonary artery O_2 saturation >70% with a relatively normal co-oximeter–measured arterial O_2 saturation). Hydrogen sulfide and sodium azide can also cause a similar pattern of oxygen saturation. Patients exposed to hydrogen sulfide may have the odor of sulfur or “rotten eggs” on the body or clothes or in a freshly drawn tube of blood.

ED EVALUATION

Whenever possible, the history should include the specific compound involved, route of exposure, any decontamination measures already undertaken, possible dose, time since ingestion or exposure, and any pre-existing allergies or chronic medical conditions. Initial physical examination should focus on vital signs (monitored frequently and serially) and the respiratory system, CV system, and CNS. The cardiac rhythm should be continuously monitored.

Determination of serum electrolytes (with calculation of the anion gap), blood glucose levels, pulse oximetry, arterial blood gas analysis, chest radiography, and 12-lead electrocardiography should be done initially and monitored frequently if clinical signs or symptoms of CN poisoning are present. Whole blood CN levels can be measured, but results usually take hours or days to obtain and thus cannot be used to guide emergent diagnosis or treatment. They are useful only to document exposure. A more practical test is the plasma lactate concentration. In the right clinical setting, a lactate concentration >8 mmol/L that is refractory to ventilation, oxygenation, and perfusion is a marker of CN toxicity (7).

KEY TESTING

- Electrolytes and blood gas for anion gap acidosis
- EKG for cardiac ischemia and dysrhythmias
- Elevated serum lactate refractory to treatment suggests CN

ED MANAGEMENT

First priority is the rapid, safe removal of victims from the scene by those with adequate training and protection. Start with airway management, 100% supplemental oxygen, cardiac monitoring, at least one large-bore intravenous line, and intravenous fluids if hypotension is present. Rescuers must not enter areas of potential HCN gas exposure without a self-contained, positive-pressure breathing apparatus. Mouth-to-mouth resuscitation should be avoided, if possible. If it is unavoidable, rescuers must be careful not to inhale the victim's expired air. Exposed skin (particularly open wounds) and eyes should be decontaminated by copiously flushing with water. Contaminated clothing should be removed and isolated.

On arrival to the emergency department (ED), care again begins with the ABCs (airway, breathing, circulation), with the particular caveat that the significantly CN-poisoned patient may deteriorate rapidly. Pulse oximetry or arterial blood gases should be monitored, and metabolic acidosis should be corrected with adequate ventilation and sodium bicarbonate if appropriate. Pulse oximetry

may be unreliable following administration of methemoglobin-inducing nitrite antidotes, and co-oximetry may be unreliable following administration of hydroxocobalamin. Once CN poisoning is suspected, either by history or by clinical presentation, specific antidotal therapy should be initiated. First-line therapy for CN is hydroxocobalamin (Cyanokit). Alternative antidotes for CN poisoning include sodium nitrite and sodium thiosulfate or sodium thiosulfate alone.
